Antimicrobial gallium-doped phosphate-based glasses of general composition $(P_2O_5)_{0.45}(CaO)_{0.16}(Na_2O)_{0.39-x}(Ga_2O_3)_x$ (where $x = 0, 0.01, 0.03$ and $0.05$) have been studied using the advanced synchrotron-based techniques of Ga K-edge X-ray absorption spectroscopy (XAS) and high-energy X-ray diffraction (HEXRD) to provide a structural insight into their unique properties. The results show that the Ga$^{3+}$ ions are octahedrally coordinated. Furthermore, substitution of Na$_2$O by Ga$_2$O$_3$ strengthens the phosphate network structure because the presence of GaO$_6$ octahedra inhibits the migration of the remaining Na$^+$ ions. The results are discussed in terms of the use of Na$_2$O-CaO-P$_2$O$_5$ glasses as controlled-delivery devices for antimicrobial Ga$^{3+}$ ions in biomedical applications. We are thereby able to relate the atomic-scale environment of the Ga$^{3+}$ ions beneficially to the glass dissolution, and thus to their ability to disrupt bacterial cell activity by usurping the role of iron.
I. INTRODUCTION

The incidence of biomaterial-centred infection, often leading to revision surgery, underlies the need to improve the properties of existing biomaterials by combining them with effective antimicrobial agents\(^1\). The causative organism in such infections is usually present as a biofilm\(^2\), a complex aggregation of microbes marked by the excretion of a protective and adhesive matrix. At present, prophylaxis, often in the form of systemically administered antibiotics, is the main weapon against bacterial infection following implant surgery\(^1\). The success of this method is limited, however, by the fact that the bacteria in biofilms are often resistant to antimicrobial agents and by the emergence of multi-resistant nosocomial pathogens such as MRSA and *Clostridium difficile*. Despite the recent increase in the number of reported MRSA and *Clostridium difficile* cases, only one new antibacterial drug with a novel mechanism of action has been introduced in the past three decades (linezolid), and very few new antibiotics are in the advanced stages of development\(^3\).

Recently, it has been demonstrated that gallium ions disrupt the iron metabolism of *Pseudomonas aeruginosa*, and exhibit antimicrobial and antibiofilm activity\(^4\). Due to the chemical similarity of Ga\(^{3+}\) with Fe\(^{3+}\) in terms of electric charge, ionic radius, electronic configuration and coordination number, gallium can substitute for iron in many biological systems. Since Ga\(^{3+}\) can not be reduced under the same conditions as Fe\(^{3+}\) and sequential redox reactions are critical for many of the biological functions of Fe\(^{3+}\), these functions are inhibited by gallium substitution\(^5\). This “Trojan horse” strategy can be exploited to disrupt iron metabolism in a wide range of bacteria. As well as *P. aeruginosa*, gallium has been shown to be effective
against the organisms causing tuberculosis\textsuperscript{6} and malaria\textsuperscript{7} in human beings, and in the treatment of \textit{Rhodococcus equi} caused pneumonia in foals\textsuperscript{8}.

The use of gallium ions as an antimicrobial agent could be significantly improved by the development of an effective means of delivery. Durable materials that can slowly release ions over long periods would be advantageous in such biomedical applications. Phosphate-based glasses (PBGs) containing calcium and sodium ions are both bioresorbable and biocompatible, and can act as a unique system for the controlled delivery of metal ions with the rate of release defined by the overall degradation rate of the glass\textsuperscript{9}. Copper and silver ions have been incorporated into PBGs, and the glasses incorporated into wound dressings to prevent infection\textsuperscript{10} and also to control urinary tract infections in patients needing long-term indwelling catheters\textsuperscript{10,11}. In the present work, we are exploring the potential for combining the antibacterial activity of Ga\textsuperscript{3+} ions with a PBG controlled delivery system.

To this end we have recently developed novel quaternary gallium-doped PBGs (1, 3, 5 mol\% Ga\textsubscript{2}O\textsubscript{3}) that have been characterised for their antimicrobial properties, physio-thermal properties, solubility and ion release. The results confirmed that the net bactericidal effect was due to Ga\textsuperscript{3+} ions, and a concentration as low as 1 mol \% Ga\textsubscript{2}O\textsubscript{3} was sufficient to mount a potent antibacterial effect. The dearth of new antibiotics in development makes gallium a potentially promising new therapeutic agent for pathogenic bacteria including \textit{MRSA} and \textit{C. difficile}\textsuperscript{12}. Moreover, gallium can inhibit bone resorption and stimulate bone formation\textsuperscript{13} and hence these novel glasses may also have applications in bone tissue engineering.

Key to a full understanding of these materials is knowledge of their atomic-scale structure. The network connectivity largely controls the overall dissolution of the glass, but this will be affected to some extent by the presence of gallium. The
extent of this effect will depend upon the structural environment of the Ga$^{3+}$ ions and the nature of their bonding interaction with the network. Hence the aim of this study is to probe the structure of the novel gallium-doped PBGs using advanced synchrotron-based techniques: high-energy X-ray diffraction (HEXRD) to provide information on the overall network structure and Ga K-edge X-ray absorption spectroscopy (XAS) to study the environment of the Ga$^{3+}$ ions.

II. EXPERIMENTAL

A. Glass preparation

Phosphate-based glasses were produced using NaH$_2$PO$_4$ (BDH, 98%), P$_2$O$_5$ (BDH, 98.5%), CaCO$_3$ (BDH, 97%) and Ga$_2$O$_3$ (Aldrich, 99.99%) as starting materials. The required amounts of each reagent were weighed into a Pt/10%Rh crucible (Johnson Matthey). The crucible was placed in a furnace preheated to 1100°C and left for 1 hour. The molten glass was then poured into a graphite mould preheated to 350°C and allowed to cool to room temperature. Four samples were prepared of general composition (P$_2$O$_5$)$_{0.45}$(CaO)$_{0.16}$(Na$_2$O)$_{0.39-x}$(Ga$_2$O$_3$)$_x$ (where $x = 0, 0.01, 0.03$ and $0.05$).

B. High-energy X-ray diffraction

HEXRD data were collected on Station 9.1 at the Synchrotron Radiation Source (SRS), Daresbury Laboratory, UK. The finely powdered samples were enclosed inside a 0.5 mm thick circular metal annulus by kapton windows and
mounted onto a flat-plate instrumental set-up. The wavelength was set at $\lambda = 0.4858$ Å and calibrated using the K-edge of a Ag foil; this value was low enough to provide data to a high value of momentum transfer ($Q_{\text{max}} = 4\pi\sin\theta/\lambda \sim 23$ Å$^{-1}$). The data were reduced using a suite of programs written in-house: the initial stage of analysis of XRD data from an amorphous material involves the removal of background scattering, normalization, correction for absorption and subtraction of the self-scattering term$^{14}$. The resultant scattered intensity, $i(Q)$, can reveal structural information by Fourier transformation to obtain the pair-distribution function:

$$T(r) = T^0(r) + \int_0^{Q_{\text{max}}} Q i(Q) M(Q) \sin(Qr) \, d(Q)$$  \hspace{1cm} (1)

where $T^0(r) = 2\pi^2 r \rho_0$ (r is the atomic separation between atoms and $\rho_0$ is the macroscopic number density) and $M(Q)$ is a window function necessitated by the finite maximum experimentally attainable value of $Q$.

Structural information can be obtained from the diffraction data by modelling the $Q$-space data and converting the results to $r$-space by Fourier transformation to allow comparison with the experimentally determined pair-distribution function$^{15}$. The structural parameters used to generate the $Q$-space simulation are varied to optimize the fit to the experimental data. The $Q$-space simulation is generated using the following equation:

$$p(Q)_{ij} = \frac{N_{ij} w_{ij}}{c_j} \frac{\sin QR_{ij}}{QR_{ij}} \exp \left[ -\frac{Q^2 \sigma_{ij}^2}{2} \right]$$  \hspace{1cm} (2)
where \( p(Q)_{ij} \) is the pair function in reciprocal space, \( N_{ij}, R_{ij} \) and \( \sigma_{ij} \) are the coordination number, atomic separation and disorder parameter, respectively, of atom \( i \) with respect to \( j \). \( c_j \) is the concentration of atom \( j \) and \( w_{ij} \) is the weighting factor. The weighting factors are given by:

\[
w_{ij} = \frac{2c_i c_j f(Q)_i f(Q)_j}{f(Q)^2} \quad \text{if } i \neq j
\]

(3)

or,

\[
w_{ij} = \frac{c_i^2 f(Q)_i^2}{f(Q)^2} \quad \text{if } i = j
\]

(4)

where \( f(Q) \) represents the \( Q \)-dependant X-ray form factors.

The errors associated with the HEXRD data arise mainly from the fitting process due to the problem of overlapping correlation shells. They have been estimated on the basis of the tolerance that a particular parameter may have without significantly changing the overall quality-of-fit. Some additional systematic error may occur from the data reduction process as a result of the approximations subsumed into the various data corrections (e.g. for Compton scattering), but past analysis of test-sample data, and data collected at different wavelengths, suggest that these errors are small compared to those arising from the numerical modelling of the experimental data.

C. X-ray Absorption Spectroscopy

Ga K-edge XAS measurements were made at room temperature on Station 16.5 at the SRS, Daresbury Laboratory, UK, with a ring energy of 2 GeV and a stored
current of 150-250 mA. The spectra were recorded in transmission mode using a double crystal Si(220) monochromator \((d = 1.92 \, \text{Å})\) and ionisation chambers to detect the incident and transmitted beam intensities. Finely-ground samples were diluted in polyethylene (Aldrich, spectrophotometric grade) and pressed into pellets to give a satisfactory edge jump and absorption. An encapsulated gallium foil and a third ionisation chamber were placed after the sample to allow an absorption spectrum of the foil to be collected simultaneously for the purpose of calibration of the energy scale. The energy scale was defined by assigning the point of maximum gradient on the absorption edge from the Ga foil to 10367 eV.

XANES spectra were collected from 50 eV below to 130 eV above the Ga K-edge in order to allow accurate background subtraction. A fine energy step of 0.4 eV was used around the edge. The data processing comprised conversion of the data to absorption versus energy, calibration of the energy scale, removal of the pre-edge background by straight-line fitting and removal of the post-edge background by fitting with a second-order polynomial. All the spectra were normalised to have an edge-step of 1. Each spectrum consisted of the sum of two scans. As well as the data from the gallium-doped PBGs, spectra were also collected from a series of crystalline reference materials containing Ga\(^{3+}\) ions in well-defined coordination geometries: quartz \(\alpha\)-GaPO\(_4\), \(\beta\)-Ga\(_2\)O\(_3\) and Ga(acac)\(_3\). The Ga(acac)\(_3\) was purchased commercially (Aldrich, 99.99%), whilst the quartz \(\alpha\)-GaPO\(_4\) and \(\beta\)-Ga\(_2\)O\(_3\) were synthesized. The quartz \(\alpha\)-GaPO\(_4\) was prepared by precipitation from an aqueous mixture of GaCl\(_3\) (Aldrich, 99.99%) and H\(_3\)PO\(_4\) by the addition of NH\(_4\)OH. The product was separated by filtration, washed and dried before heating to 800 °C to remove ammonium and hydroxyl groups\(^{16}\). The \(\beta\)-Ga\(_2\)O\(_3\) was prepared by calcination of Aldrich 99.99% Ga\(_2\)O\(_3\) overnight at 1000 °C\(^{17}\). The gallium foil used for the calibration of the energy
scale was prepared by hot-pressing Aldrich 99.99% Ga metal between two sheets of filter paper and laminating the resulting construct in plastic.

Data were also collected in the EXAFS region for selected samples. The EXAFS spectra were collected over the range $k = 3 - 18 \text{ Å}^{-1}$ with a step of 0.04 Å$^{-1}$ and a counting time of 1 to 10 s per point varying as $k^3 (k = \sqrt{2m_e/h^2(E - E_0)})$, where $m_e = \text{mass is the rest mass of the electron, } E = \text{energy and } E_0 = \text{energy of the absorption edge.}$ The programs EXCALIB, EXSPLINE and EXCURV98 were used to extract the EXAFS signal and analyse the data. Least squares refinements of the structural parameters of our samples were carried out against the $k^3$-weighted EXAFS signal to minimize the fit index, FI,

$$FI = \sum k^3 (\chi^T_i - \chi^E_i)^2$$

(5)

where $\chi^T_i$ and $\chi^E_i$ are the theoretical and experimental EXAFS, respectively. The results of the refinements are reported in terms of the discrepancy index, $R_{di}$.

$$R_a = \frac{\int (\chi^T(k) - \chi^E(k))k^3 dk}{\int \chi^E(k)k^3 dk} \times 100\%$$

(6)

Quartz $\alpha$-GaPO$_4$ was run as reference material to check the validity of our data analysis and also to allow refinement of the parameter AFAC (defined as the proportion of the photo-electrons taking part in an ‘EXAFS-type’ scattering event).
III. RESULTS

A. High-energy X-ray diffraction

Fig. 1 shows the HEXRD data from the PBGs containing 0 and 5 mol% Ga$_2$O$_3$. HEXRD data from an amorphous material can give information on the atomic distances and occupancies within its structure. Such information is contained in the pair-distribution functions (PDFs) which are obtained by Fourier transformation of the corrected scattering data. The pair-distribution functions shown in Fig. 1 (b) were obtained by Fourier transformation of the curves in Fig. 1 (a). They exhibit four features that are characteristic of the structure of a PBG: an intense peak at 1.55 Å due to P–O bonding, a peak at 2.45 Å attributed mainly to the O--O nearest-neighbour distance, a shoulder on the low-$r$ side of this peak due to Ca–O and Na–O bonding, and a peak at 2.95 Å assigned to the P--P distance$^{19}$.

In order to identify the atomic correlations associated with gallium, we take a difference between the PDF from the glass containing no Ga$_2$O$_3$ and that containing 5 mol% Ga$_2$O$_3$. The resulting difference PDF is shown in Fig. 2. This method does not completely isolate the correlations associated with gallium, even assuming that the two samples are structurally equivalent except for the substitution of Na$_2$O by Ga$_2$O$_3$, because the X-ray weighting factors (i.e. a measure of the strength with which a given correlation scatters X-rays) for all the pair-wise correlations change as a function of glass composition; as a consequence, the other atomic correlations (mainly P–O, Na–O, Ca–O, O--O and P--P) do not completely cancel out. However, this difference method may reasonably be applied here because the compositions of the glass studied are such that the residual peaks due to the P–O, Na–O, Ca–O, O--O and P--P
correlations are small compared to those involving the gallium ions. This is illustrated by Fig. 3 which shows the X-ray weighting factors for the difference PDF, obtained by calculating the approximate weighting factors for each correlation at the two compositions and subtracting. The weighting factors used are approximate because they were calculated using the atomic number for each element rather than its X-ray form factor \((i.e. \text{ using } F_{ij} = 2c_i c_j Z_i Z_j \text{ and } F_{ii} = c_i^2 Z_i^2)\), where \(F_{ij}\) is the weighting factor for the \(i-j\) correlation, and \(c_i\) and \(Z_i\) are the concentration and atomic number of element \(i\), respectively\(^{20}\). Examining Fig. 3, it can seen that the Ga–O and Ga–P correlations are expected to contribute the most to the difference PDF. Indeed, the difference PDF does exhibit two intense peaks at 1.93 and 3.19 Å, respectively assigned, on the basis of the difference weighting factors, to Ga–O and Ga–P distances. Although no further quantitative information may be derived from the difference PDF, for the reason described above, the determination of the Ga–O and Ga–P distances is nonetheless valuable to the overall characterisation of the glass structure, and vital for the modelling of the HEXRD data.

Structural parameters \((i.e. \text{ atomic distances, coordination numbers and the degree of disorder within a particular atomic correlation})\) can be obtained from HEXRD data by modelling the pair-distribution function. Using the peak assignments described above, we have simulated the PDFs shown in Fig. 1; the resultant structural parameters are given in Table I.

**B. X-ray absorption spectroscopy**

Extended X-ray absorption fine structure, EXAFS, spectroscopy provides information on the local structure around a given probe element by simulating the
experimental data using routines based upon curved-wave theory. Here we collected Ga K-edge data from the glass samples containing 3 and 5 mol% Ga$_2$O$_3$; the structural parameters obtained from the simulation of the data are given in Table II. Two atomic correlations were observed, one at 1.93 Å due to a Ga–O distance and one at 3.18 Å ascribed to a Ga–P distance. These distances show excellent agreement with those determined from the HEXRD data. The structural parameters from the longer Ga–P correlation should be treated as less reliable than those from the Ga–O shell because no account of multiple scattering effects was taken during the data analysis. These effects may become increasingly significant beyond nearest-neighbour distances but cannot accurately be modelled in the case of an amorphous material.

X-ray absorption near-edge spectroscopy, XANES, spectra can also give information on the coordination environment of a given probe atom, often by comparison of the spectra with those from materials containing the probe atom in a well-defined structural site. In this case, we collected data with higher energy resolution in the vicinity Ga K-edge from reference materials, shown in Fig. 5 (a), and the glass samples containing 1, 3 and 5 mol% Ga$_2$O$_3$, shown in Fig. 5 (b). The reference materials were chosen to have a range of gallium coordination environments: quartz α-GaPO$_4$ contains tetrahedrally coordinated gallium, β-Ga$_2$O$_3$ an equal mixture of tetrahedral and octahedral gallium, and Ga(acac)$_3$ octahedral gallium. Fig. 5 (a) shows that for the octahedrally-coordinated gallium a broad feature at ~10377 eV is observed, whilst for the tetrahedrally-coordinated gallium a distinct two-humped curve is seen in the same region with features centred at slightly higher and lower energy. The XANES spectrum from β-Ga$_2$O$_3$, the mixed-site material, contains features as observed in both the single-site materials. These qualitative observations are in agreement with previous studies which demonstrated...
that different coordination sites could be distinguished using Ga K-edge XANES\textsuperscript{17,22,23}. The XANES spectra from the gallium-doped PBGs exhibit no variation as a function of composition and are similar to that measured from Ga(acac)\textsubscript{3}.

\section*{IV. DISCUSSION}

\subsection*{A. Cation coordination}

Gallium ions in phosphate-based materials display an extraordinarily rich chemistry, adopting octahedral, tetrahedral and trigonal bipyramidal coordination. Of the crystalline anhydrous gallium phosphates, GaPO\textsubscript{4} has gallium in a tetrahedral environment\textsuperscript{16}, Ga(PO\textsubscript{3})\textsubscript{3} contains octahedral gallium\textsuperscript{24} and (NH\textsubscript{4})\textsubscript{3}Ga\textsubscript{2}(PO\textsubscript{4})\textsubscript{3}\textsuperscript{25} trigonal bipyramidal gallium. The diversity of gallium chemistry is further illustrated by the open framework structure of Na\textsubscript{3}Ga\textsubscript{4}O(OH)(H\textsubscript{2}O)(PO\textsubscript{4})\textsubscript{4}H\textsubscript{2}O which contains all three coordination geometries of gallium\textsuperscript{26}. The situation is similar in the amorphous state. HEXRD has previously been used to demonstrate that the coordination geometry of gallium varies as a function of composition in Ga\textsubscript{2}O\textsubscript{3}-P\textsubscript{2}O\textsubscript{5} glasses with mostly tetrahedral gallium present at the pyrophosphate composition (Ga\textsubscript{4}(P\textsubscript{2}O\textsubscript{7})\textsubscript{3}) and solely octahedral gallium present at the metaphosphate composition (Ga(PO\textsubscript{3})\textsubscript{3})\textsuperscript{27}. Ga K-edge EXAFS and \textsuperscript{71}Ga MAS NMR have also been used to identify octahedral, tetrahedral and trigonal bipyramidal coordinated gallium in Na\textsubscript{2}O-Ga\textsubscript{2}O\textsubscript{3}-P\textsubscript{2}O\textsubscript{5} glasses\textsuperscript{28}.

The XANES spectra presented here from the gallium-doped PBGs exhibit no variation as a function of composition and show one broad feature that is similar in
shape, intensity and magnitude to that observed for Ga(acac)$_3$, suggesting that the Ga$^{3+}$ ions in all the glass samples are octahedrally coordinated. Further evidence for octahedral coordination is provided by the EXAFS spectra and HEXRD data. Firstly, the EXAFS-derived Ga–O coordination numbers for the 3 and 5 mol% Ga$_2$O$_3$ samples are 6, within experimental error. Secondly, and more importantly, the measured Ga–O and Ga···P distances of 1.93 and 3.19 Å, respectively, show excellent agreement with those expected for octahedral gallium in a phosphate-based material. Ga–O distances show a strong correlation with coordination number: typical Ga–O distances for tetrahedral gallium fall in the range 1.82–1.84 Å, those for five coordinate gallium in the range 1.88–1.92 Å and those for octahedral gallium 1.94–1.99 Å$^{29}$. Furthermore, in phosphate-based materials, since the next nearest-neighbour atom is phosphorus which is part of the same anion as the nearest-neighbour oxygen atoms, one might expect a weaker correlation between metal coordination number and metal-phosphorus distance. In crystalline Ga(PO$_3$)$_3$, which contains octahedral gallium, the Ga–O and Ga···P distances are 1.95 and 3.24 Å, respectively$^{24}$, whereas the Ga–O and Ga···P distances for tetrahedral gallium in GaPO$_4$ are 1.85 and 3.07 Å, respectively$^{16}$. Similar distances are observed in the amorphous state. Hoppe et al.$^{27}$ found average Ga–O and Ga···P distances of 1.93 and 3.20 Å, respectively, for octahedral gallium in Ga(PO$_3$)$_3$ glass and distances of 1.87 and 3.05 Å, respectively, in Ga$_4$(P$_2$O$_7$)$_3$. The latter material exhibited a Ga–O coordination number of 4.6, suggesting that it contained mostly tetrahedral gallium as suggested by the shortening of the average Ga–O and Ga···P distances. The Ga–O and Ga···P distances measured here show very close agreement with those of Hoppe measured for gallium in an octahedral environment in a phosphate-based glass. However, the Ga–O coordination numbers determined here from the HEXRD data are closer to 4 than 6. This
discrepancy can be explained by considering further the results of Hoppe. In that study, an asymmetric Ga–O peak, which had a tail extending to the high-\( r \) side of the mean position of \(~1.9\) Å, was observed for both compositions. Hoppe was able to simulate this peak shape with two Ga–O correlations because the high-\( r \) tail was well-resolved from the main O–O peak at \(~2.5\) Å. In our case, the situation is complicated by the presence of Na–O and Ca–O correlations at \(~2.35\) Å which render an accurate simulation of any high-\( r \) tail of the Ga–O peak impossible. Hence, the Ga–O coordination numbers measured here using HEXRD suggest that there is significant structural disorder around the gallium site which leads to a high-\( r \) contribution to the Ga–O peak which can not be accurately modelled in this data. This explanation is supported by the high EXAFS Debye-Waller factors for the Ga–O correlation which also suggest disorder in the GaO\(_6\) octahedra.

The structural parameters derived from the HEXRD data also give information on the coordination of the Na\(^+\) and Ca\(^{2+}\) cations. The relevant parameters, shown in Table I, are typical of those determined by diffraction methods for PBGs containing Na\(^+\) and Ca\(^{2+}\) ions, with Na–O and Ca–O nearest-neighbour distances of close to 2.34 and 2.38 Å, respectively, and coordination numbers of \(~4\) for both correlations\(^{19,30}\). The important result here is that no variation in the coordination of the Na\(^+\) and Ca\(^{2+}\) cations as a function of gallium content is observed.

\[ \text{B. Phosphate network} \]

Phosphate glasses are often characterised in terms of the connectivity of the PO\(_4^{3-}\) tetrahedra that comprise the back-bone of their structures\(^{19}\). Predictions can be made concerning the phosphate connectivity on the basis of the glass composition,
specifically the O/P ratio\textsuperscript{19}. The glasses studied here have O/P ratios in the range 3 < O/P < 3.5, where the upper and lower limits in this range are the O/P ratios for the pyrophosphate ($P_{2}O_{17}^{4-}$) and metaphosphate ($PO_3^{−}$) compositions, respectively. Since metaphosphate glasses have structures consisting of rings and infinite chains of $PO_4^{3−}$ tetrahedra and pyrophosphate glasses contain $P_{2}O_{17}^{4−}$ dimers, the glasses studied here are expected to contain rings and shorter, phosphate chains with the presence of only two types of phosphate species, \textit{i.e.} $PO_2^{−}$ middle groups and $PO_3^{2−}$ chain-terminating end groups.

The structural parameters derived from the HEXRD data given in Table I describe both the individual $PO_4^{3−}$ tetrahedra and their connectivity. Two P–O bond distances are used in the simulation of the PDF data, one at 1.60–1.61 Å ascribed to bonds to oxygen atoms that are shared between connected $PO_4^{3−}$ tetrahedra (\textit{i.e.} bridging oxygens, BOs) and one at 1.49 Å ascribed to bonds to non-bridging oxygen atoms (NBOs). For all three samples, a P–O coordination number of ~4 is observed as expected for structures based on $PO_4^{3−}$ tetrahedra. No significant variation in the numbers of P–NBO and P–BO bonds is seen between samples, however, despite the variation in O/P ratio as a function of composition, \textit{i.e.} 3.11, 3.18 and 3.22 for the 0, 3 and 5 mol% $Ga_2O_3$ samples, respectively, which should coincide with a change in connectivity within the phosphate network. This is most probably due to the difficulty in accurately modelling the two overlapping P–NBO and P–BO correlations, which highlights the limitations of the method.

The P--P coordination numbers in Table I can be compared to the expected values calculated on the basis of composition. The expected P--P coordination numbers for the 0, 3 and 5 mol% $Ga_2O_3$ samples are 1.8, 1.6 and 1.6, respectively, which are in reasonable agreement with the experimental values of 1.8, 1.7 and 1.7 in
Table I. Unfortunately, the errors of ±0.3 associated with the experimental coordination numbers are larger than the expected decrease of 0.2 as a function of gallium content which means that we are limited in whether the experimentally observed decrease is significant. To help visualize the structural significance of the P--P coordination numbers, $N_{pp}$, we can calculate the average phosphate chain lengths, $L$, assuming that the structures are based entirely of linear chains composed of only $–\text{PO}_2–$ middle groups and $–\text{PO}_3^{2–}$ end groups with an absence of rings:

$$L = \frac{2}{2 - N_{pp}}$$  \hspace{1cm} (7)

Using the P--P coordination numbers calculated from the glass compositions, we arrive at average phosphate chain lengths of ~9, ~6 and ~5 for the 0, 3 and 5 mol% Ga$_2$O$_3$ samples, respectively. This result shows that substituting only 5 mol% of the Na$_2$O with Ga$_2$O$_3$ in (P$_2$O$_5$)$_{0.45}$(CaO)$_{0.16}$(Na$_2$O)$_{0.39}$ glass can have a radical effect on its network structure.

To understand further the structural effects of adding Ga$_2$O$_3$ to a (P$_2$O$_5$)$_{0.45}$(CaO)$_{0.16}$(Na$_2$O)$_{0.39}$ glass, it is important to consider the role of the NBO atoms. In phosphate-based glasses between the pyrophosphate and metaphosphate compositions, the chains of PO$_4^{3–}$ tetrahedra are usually linked by bonding interactions between the cations and the NBOs of the phosphate chains. In regard to this cross-linking of the phosphate chains, it is useful to consider the number of NBOs available to coordinate the cations. The number of NBOs per cation, $N_{Me}$, can easily be calculated from the glass composition$^{31}$. For the glasses containing 0, 3 and 5 mol% Ga$_2$O$_3$, there are 2.13, 2.26 and 2.34 $N_{Me}$, respectively. Since the experimental
results presented here exhibit no variation in Na–O and Ca–O coordination numbers as a function of glass composition, the $N_{Me}$ values indicate that substitution of Na$_2$O with Ga$_2$O$_3$ results in more NBOs available to coordinate the gallium ions, resulting in the formation of GaO$_6$ octahedra. These GaO$_6$ octahedra block the migration of the remaining Na$^+$ ions and increase the stability of the glass. A similar effect has been observed in phosphate glasses containing a few mol% of Fe$_2$O$_3$, where FeO$_6$ octahedra hinder the migration of other cations$^{32}$.

The effect described, combined with the good glass-forming ability of gallium$^{27,33}$ and the covalent nature of Ga–O–P bonding relative to Na–O–P bonding$^{33}$, provide a structural basis for the observed increase in chemical durability of Na$_2$O-CaO-P$_2$O$_5$ glasses when Ga$_2$O$_3$ replaces Na$_2$O$^{12}$. This is of direct relevance to the use of Na$_2$O-CaO-P$_2$O$_5$ glasses as controlled-delivery media for antimicrobial Ga$^{3+}$ ions in biomedical applications. The results suggest that the concentration of Ga$_2$O$_3$ will be important, not only in terms of the total number of Ga$^{3+}$ ions available for release, but also in terms of the overall stability and degradation rate of the glass matrix and therefore the rate with which those ions are released into body fluids.

V. CONCLUSION

The results of our structural study of antimicrobial gallium-doped phosphate-based glasses of general composition (P$_2$O$_5$)$_{0.45}$(CaO)$_{0.16}$(Na$_2$O)$_{0.39}$x(Ga$_2$O$_3$)$_x$ (where x = 0.01, 0.03 and 0.05) show that the Ga$^{3+}$ ions occupy octahedral sites with respect to oxygen in all samples. Comparison of the HEXRD data with that from the glass containing no gallium reveals that the Ga$^{3+}$ ions enter the phosphate network and reduce the average phosphate chain length. Substitution of Na$_2$O with Ga$_2$O$_3$ in Na$_2$O-
CaO-P$_2$O$_5$ glasses also increases the stability of the structure via the formation of GaO$_6$ octahedra which block the migration of the Na$^+$ ions. This result is of direct relevance to the use of Na$_2$O-CaO-P$_2$O$_5$ glasses as controlled delivery media for antimicrobial Ga$^{3+}$ ions in biomedical applications, suggesting that the level of Ga$_2$O$_3$ doping will affect both the concentration of Ga$^{3+}$ ions available for release, and the overall stability and rate of degradation.

FIG. 1: HEXRD data from the $(P_2O_5)_{0.45}(CaO)_{0.16}(Na_2O)_{0.39-x}(Ga_2O_3)_x$ glasses. (a) $Q$-space interference functions from the $x = 0$ (lower curve) and $x = 0.05$ (upper curve) samples, and (b) the real-space pair-distribution functions obtained by Fourier transformation of the $Q$-space data (solid lines) together with the simulations (dashed curves). Note that in each frame the upper curves have been offset for illustrative purposes.

FIG. 2: Difference pair-distribution function showing atomic correlations involving gallium (obtained by taking the difference between the pair-distribution functions shown in Fig. 1).

FIG. 3: Approximate X-ray scattering weighting factors for the difference pair-distribution function shown in Fig. 2.

FIG. 4: Ga K-edge EXAFS spectra from the $(P_2O_5)_{0.45}(CaO)_{0.16}(Na_2O)_{0.39-x}(Ga_2O_3)_x$ glasses. (a) $k^3$ weighted EXAFS (solid lines) with theoretical fits (dashed lines) from the $x = 0.03$ (lower curves) and $x = 0.05$ (upper curves) samples, and (b) Fourier transforms of these EXAFS spectra (solid lines) with theoretical fits (dashed lines). Note that in each frame the upper curves have been offset to aid clarity.

FIG. 5: Ga K-edge XANES spectra from (a) crystalline reference materials: quartz $\alpha$-GaPO$_4$ (solid line), Ga(acac)$_3$ (dashed line) and $\beta$-Ga$_2$O$_3$ (dotted line), and (b) $(P_2O_5)_{0.45}(CaO)_{0.16}(Na_2O)_{0.39-x}(Ga_2O_3)_x$ glasses: $x = 0.01$ (solid line), 0.03 (dashed line) and 0.05 (dotted line).
Figures

FIG1:

(a) Plot of $i(Q)$ against $Q$ (Å$^{-1}$) with $Q$ ranging from 0 to 22. The graph shows peaks at certain values of $Q$.

(b) Plot of $T(r)$ (atoms Å$^{-2}$) against $r$ (Å) with $r$ ranging from 0 to 5. The graph displays oscillatory behavior with maxima at specific distances. The dotted line represents a reference or reference curve for comparison.
