Exploring the Dynamics of Journal Citations: Modelling with S-Curves[1]

This paper reports on an exploratory analysis of the behaviour of citations, i.e., pattern of obsolescence, for management science papers over a fourteen year period. It addresses three questions: i) can collections of papers from the same journal all be modelled using the same obsolescence function? ii) Can we identify specific patterns of behaviour such as "sleeping beauties" or "shooting stars"? iii) Can we predict the number of future citations from the pattern of behaviour in the first few years? Over 600 papers published in six leading journals are analysed using a variety of s-curves.

Keywords: citations, gamma, Gompertz, Pearl-logistic, negative binomial, s-curve, Weibull

---

1. Introduction

There is currently much interest in measuring the quality of academic research whether at the institutional, journal or personal level. In the main, this has been done through peer review (also known as stated preference) where a group of academics produce a ranking of journals. Many of these rankings have been collected together on a website by Harzing (2005) and a combined ranking based on statistical analysis has been produced by Mingers and harzing (2005). The alternative approach is to use revealed preference measures based on actual publication behaviour, especially using the paper citation data available from the ISI index (Tahai and Meyer, 1999; Baden-Fuller et al., 2000; DuBois and Reeb, 2000).

This paper reports on an exploratory analysis of the dynamic behaviour of citations for a sample of management science papers all published in 1990. Typically, although there is much variation as we shall see, the number of citations for a paper is small to begin with; rises to a peak in response to other citations; and then subsides as the paper's material becomes obsolete. If we look at the cumulative citations for a typical paper then we see an s-shaped curve similar to growth curves or cumulative probability curves. These are called obsolescence functions in this context by Burrell (2001). Two obvious exceptions to this pattern are those papers that are never cited at all (surprisingly sometimes as many as 20% of papers in a journal); and those seminal papers that continues to receive many citations for very long periods of time.

This exploration was motivated by three questions:

1. To what extent can collections of papers (e.g., all from one journal) be modelled by the same obsolescence functions? This is of theoretical interest since Burrell (2002; 2003) assumed this was the case in developing a Poisson-gamma model for the process of citation generation, and Mingers and Burrell (2005) fitted a cumulative gamma distribution to empirical data.
2. Can we identify different patterns of behaviour for particular types of papers? For example, "sleeping beauties" (Van Raan, 2004) which remain uncited for some time before suddenly becoming popular, perhaps because they were ahead of their time; or "shooting stars" which are

[1] I would like to acknowledge the work of Hajir Karbassi in rigorously collecting the data.

heavily cited initially but die quickly perhaps because they were part of a fad. If new patterns emerge can we explain what generates them?

3. To what extent can the number of future citations be predicted given the pattern of citations over the first few years? This is of particular interest for quality exercises such as the UK's RAE where none of the papers evaluated will be older than seven years and so will still be young within their citation lifespan.

To address these questions a study was undertaken to fit a variety of s-curves to sets of empirical data, that is the citation histories of management science papers. The next section discusses the approach taken, and the third section reports on empirical results.

2. Methodology

The data set consisted of a sample of over 600 papers published in 1990 giving a fourteen year history of citation behaviour. When the sample was taken this was felt to be long enough for most papers to have completed their citations but not so long that there would have been significant changes in academic citation behaviour. However, once the data was analysed it became clear that this was really too short a period. The sample was all those papers published in six leading management science journals: *Management Science* (ManSci), *Operations Research* (OpsRes), *Decision Science* (DecSci), *European J. Operational Research* (EJOR), *J. Operational Research Society* (JORS), and *Omega* (Omega). These were selected for their variety on several factors – level of prestige and quality; prevalence of heavily mathematical articles; US versus European; narrowness and width of coverage. The number of citations for each journal over the full 14 year period 1991-2004 was tabulated and the means and standard deviations are shown in Table 1, and histograms in Figure 1.

Two comments should be made about the data. i) At first all document types from a journal were recorded. However, with JORS and EJOR there were large numbers of book reviews which virtually all received zero citations. Whilst a book review could be cited it is very rare. Other journals, especially ManSci and OpsRes did not have reviews and so had a much smaller proportion of zero citations. To avoid this bias, only documents of type article, editorial or letter were recorded. ii) With the ISI database selection of a year in the database limits does not correspond exactly with the actual year of publication. For JORS for example, selecting "1990" picks up some papers from the end of 1989 and excludes some from the end of 1990. This required considerable manual intervention.

	*JORS	Omega	EJOR	DecSci	OpsRs	ManSci
Mean	7.3	7.2	11.3	11.1	14.7	38.6

% zero cites	18	22	14	12	10	5
Max. cites	176	87	140	66	277	181

Table 1 Summary Statistics for the Number of Citations per Paper

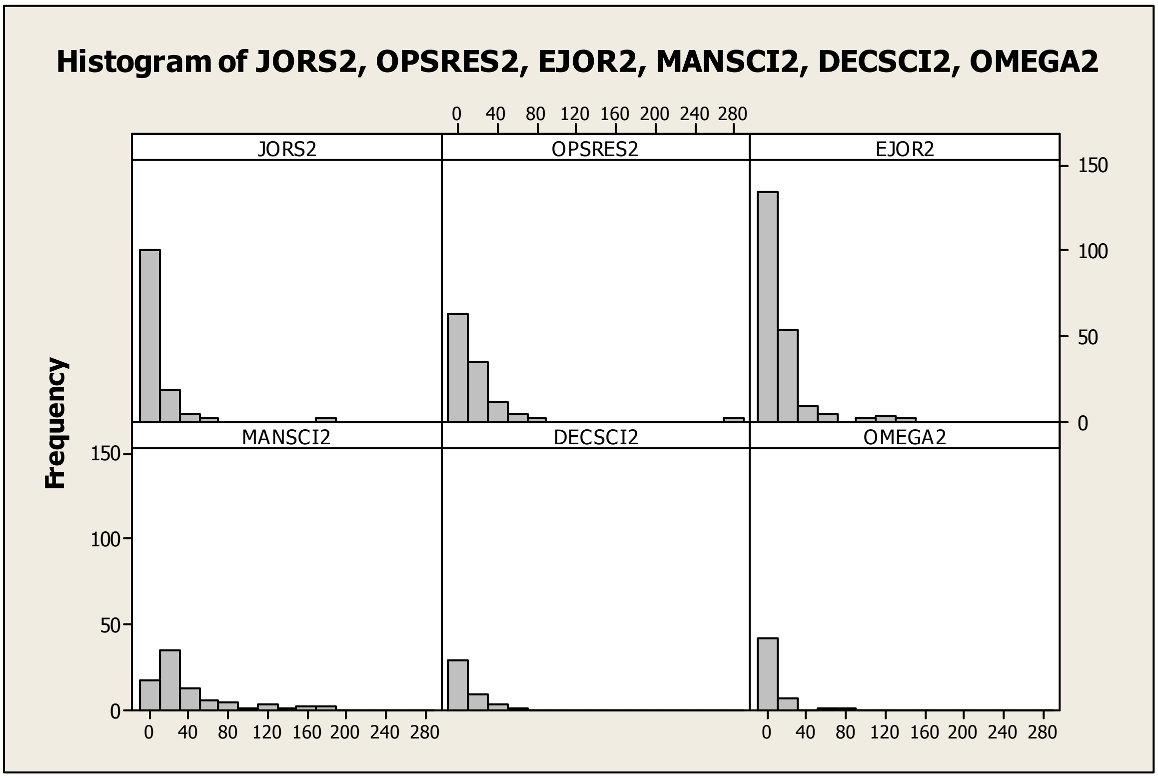

Figure 1 Histograms of the Distributions of Number of Citations

The mean number of citations (over 14 years) varied significantly from 7 (JORS and Omega) to 39 (ManSci). All the distributions were extremely skewed with variances up to 40 times the mean. The maximum number of citations for a paper ranged from 66 (DecSci) to 277 (OpsRes) although these were to some extent outliers. One interesting, and perhaps surprising, fact is the number of papers that were *never* cited during the period of observation. In each case (except ManSci) the modal value of the distribution of number of citations was in fact zero and the % of zero cites ranges from 5% (ManSci) to 18% (JORS) and 22% (Omega).

The next stage was to decide which s-curves were to be fitted to the data. Within the domains of technological forecasting and marketing, where s-curve fitting has primarily developed, the most common curves used are the logistic and the Gompertz. (Martino, 1983). However, there are many curves that could be used[2] and in fact Meade and Islam (1998) identify 29 different ones. Meade and Islam classify their models into three classes – symmetric, asymmetric and flexible depending on behaviour around the point of inflection. The point of inflection of the s-curve (which is a cumulative curve) is equivalent to the point of maximum citation generation, that is the mode of the corresponding probability density function. Symmetrical models have a fixed point of inflection which occurs at 50% of the eventual total citations. The growth and decline are symmetrical about this point. Asymmetrical models typically have their inflection point at less than 50% with a faster growth than decline. The underlying pdf is positively skewed. Flexible models can have variable inflection

[2] Indeed, almost all probability distributions have appropriately shaped cumulative distributions

points, some even being greater than 50%. The underlying pdf's can take on a range of shapes both symmetrical and skewed. For this research one member of each of these classes was selected – the Pearl logistic (symmetrical), the Gompertz (asymmetrical) and the Weibull (flexible). The gamma distribution was also included as this had been used in previous work as mentioned above. The gamma is also a flexible distribution similar in many respects to the Weibull. Details of these curves are shown in Appendix A.

The fitting process was straightforward using the Excel Solver. This was used to estimate parameter values for each curve that minimised the sum of squared errors (SS) from the empirical cumulative citation data. This method is biased towards the higher values of the curve but this was felt to be acceptable especially given the importance and difficulty of estimating the upper limit of the s-curves (see below). There was a practical problem in that sometimes the Solver would become stuck in a local optimum for a particular curve. This was easily detectable as the fitting was done manually and graphs showed where the curves were not fitted properly. Manually setting starting values always resolved the problem. In many cases the fitting process was duplicated and the results were within 0.01%.

A further validation method was used by comparing the fitted parameters. The Weibull and the gamma, particularly, tend to give very similar results. In each case it is possible to estimate the time of inflection from the fitted parameters (see Appendix A for the formula) and a plot of one against the other forms an almost perfect straight line (r=0.996). Any deviations were investigated and re-fitted. A similar approach was used with the Pearl and Gompertz although the relationship had more variability.

3. Empirical Results

3.1 Fitting s-curves to collections of papers

One of the first steps was to simply look at the pattern of citations over time for each journal and the total. This is shown in Table 2.

	1	2	3	4	5	6	7	8	9	10	11	12	13	14

Table 2 Number of citations per period after publications (shaded boxes show modal period)

A bar chart is shown in Figure 2.

All the journals show a clear pattern of citations as expected. Citations rise to a peak most commonly after about six years although there is some variation between journals. There is then something of a plateau before numbers begin to reduce. ManSci particularly maintains a high level for a long period – from 262 in period 4 through to 265 in period 14. It was certainly surprising to me that citations should still be high over such a long period. Indeed, if one projects forward (see later) 15 years there would still be around 120 citations in total.

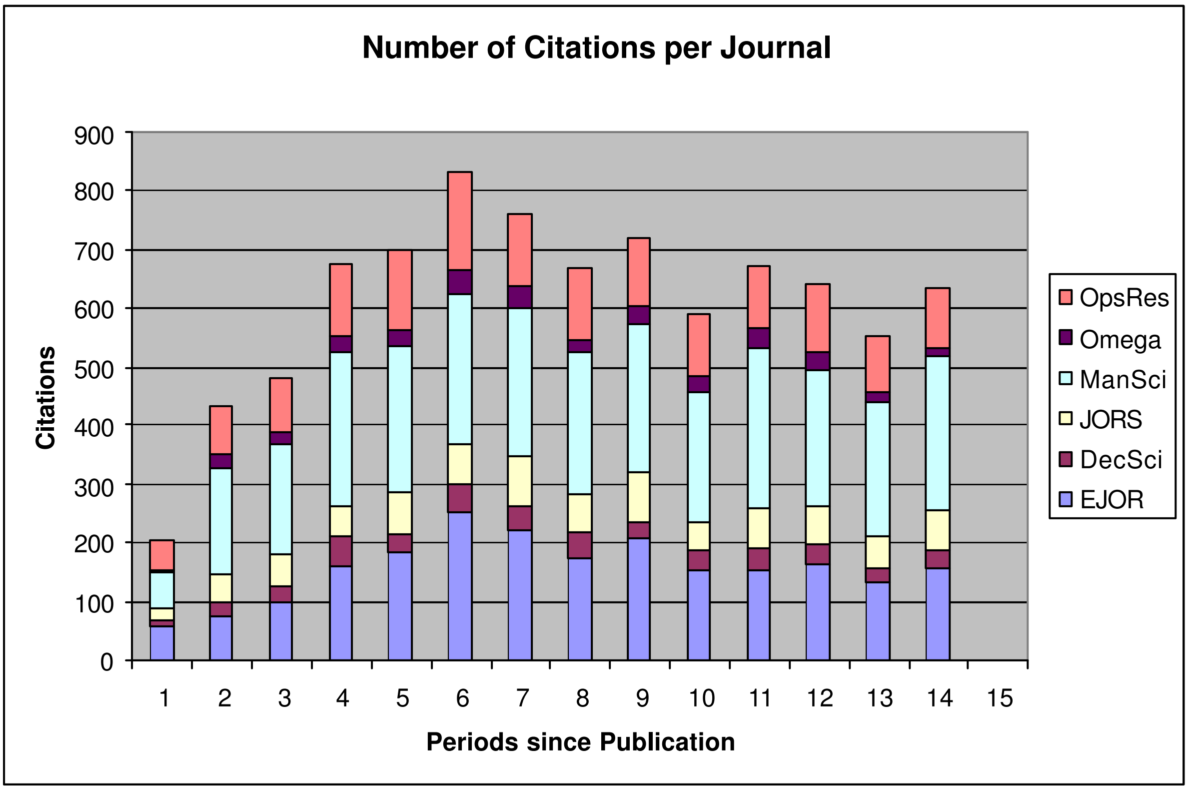

Figure 2 Citations per Journal per period

This data was the first to be used for s-curve fitting, initially for the total set of citations, and then splitting it down by journal, to begin to answer the first of the research questions.

Table 3 S-Curves fitted to the collections of journals (shaded boxes show the best fits)

Table 3 shows, for each journal separately and for the total citations, the fitted parameters for the fours different curves. It also shows the sum of squares (ss) as a measure of goodness of fit.

Looking firstly at the total citations the fitted curves are shown in Figure 3. It appears from this that all the curves fit reasonably well although they give quite different future projections with the Pearl logistic the lowest and the gamma the highest. However, looking in more detail at the year on year citations in Figure 4 shows that certain curves fit the data much better than others. The Pearl curve is always a symmetrical curve with the point of inflection (maximum growth) occurring when it is at 50% of its maximum value (see Appendix 1). Clearly the citation data is not symmetrical but strongly positively skewed. The Gompertz curve is not symmetrical but it also has a fixed inflection point at the same time as the Pearl curve but with a lower cumulative value. This too does not fit the data well.

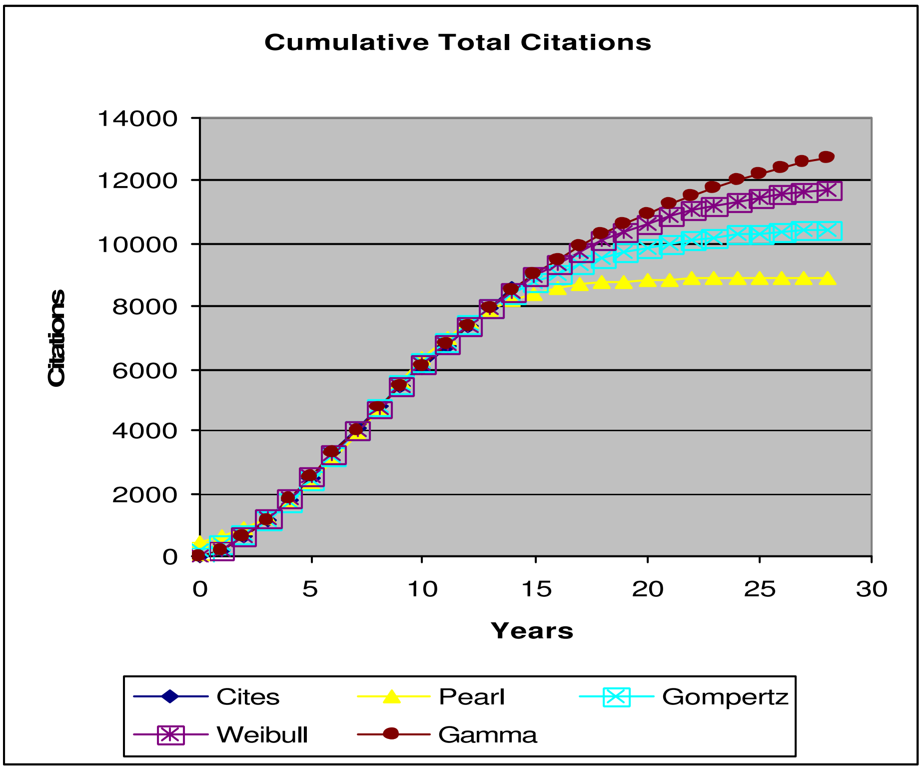

Figure 3 Cumulative Citations for all Journals

In contrast, both the Weibull and gamma curves are very flexible in their shapes and points of inflection and can be fitted well to the data. This is reflected in the SS where the Pearl is worst with 880k, then the Gompertz with 192k, the Weibull 39k and the gamma is best with 29k. The gamma estimate of the eventual total is 14,000 (after about 50 years) while the Weibull is 12,000 (after 40).

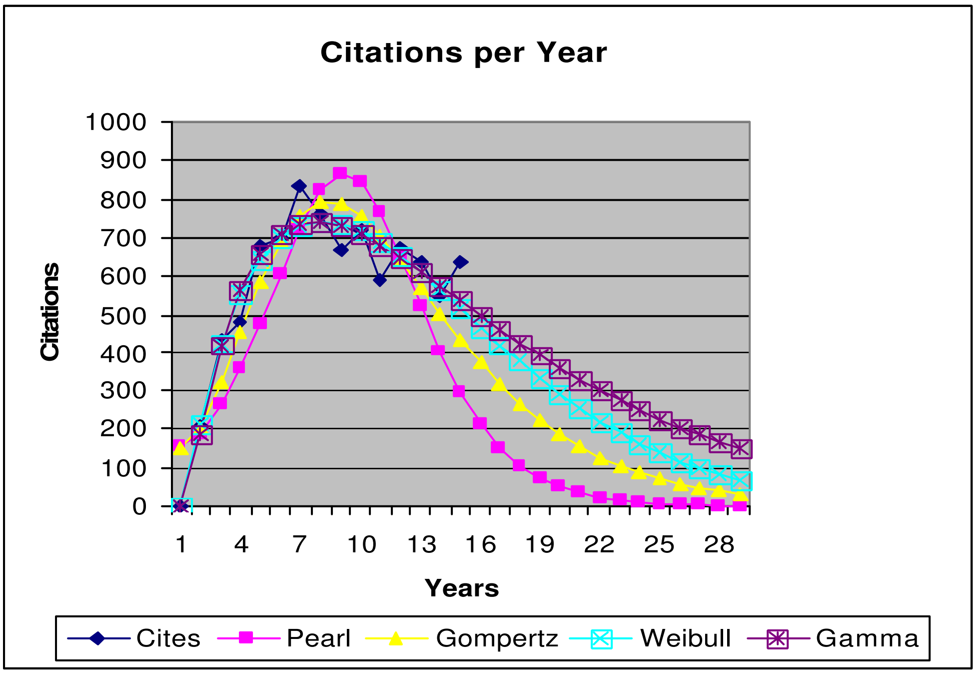

Figure 4 Citations per year for all Journals

Moving down to the individual journals, we can see (in Table 3) that in four out of the six the gamma is best, with the Weibull being marginally best in the other two – Omega and JORS.

These results are broadly in line with those of Mingers and Burrell (2005). In that paper obsolescence functions (i.e., s-curves) were not fitted directly to the data but instead to curves derived from the additional citations distribution tested in the paper. This in turn was based on a gamma-Poisson model for the underlying process of citation generation combined with some form of obsolescence function, the particular form being estimated from the data. Several different obsolescence functions were tested including those used in this paper. The results showed the gamma function to be the best overall in terms of lowest total SS, and individually best for ManSci. The Weibull was second best overall and individually best for OpsRes and EJOR. One other curve – the SPSS s-curve – had inconsistent results being best for certain journals and very poor on others. The general conclusion, therefore, is that the gamma distribution is a good fit for collections of papers which are likely to show significant skew over time. The other interesting result is simply the length of time over which well-cited papers carry on getting cited.

3.2 Fitting s-curves to individual papers

The next stage of the analysis was to move down a level to individual papers and see whether particular patterns emerged at this level in order to address research question one.

The first problem was which papers to analyse. Clearly there was no point in using papers that were very rarely cited and as a cut-off only those with 15 or more citations were considered – equivalent to averaging one per year. Although this seems fairly modest it removed over 75% of the papers as shown in Table 4. This differed significantly between journals – 37% for ManSci, but over 90% for JORS and Omega.

	ManSci	JORS	EJOR	OpsRes	DecSci	Omega	Total
< 15	37%	91%	81%	75%	77%	90%	469
Still Active	55%	5%	14%	16%	18%	6%	110
Complete	8%	4%	5%	9%	5%	4%	36

Table 4 Papers Complete or still Active

On fitting curves to the remaining papers a further problem emerged – estimates of the upper bound. In some series, especially where citations rates were still high and it was not clear from the data whether the turning point had yet been reached, the different curves would generate hugely different upper limits. Sometimes these would be four or five times the number of citations so far recorded. This is generally a significant problem in fitting s-curves to sets of data that are not yet complete. In fact, Martino (1983), within the context of technological forecasting, argues that the upper limits should always be determined manually having regard to ultimate technological or economic constraints rather than be estimated from the data. However in our case this does not seem possible. How could we put a sensible limit on the total number of citations that any paper could possibly receive? Whilst most highly cited papers would go into the hundreds[3], a particular paper could go into the thousands. Equally, it seems impossible to decide on some arbitrary length of time after which citations would finish. Experiments were tried constraining the estimate of the upper limit to two or three times the current level but these just distorted the fitting and still seemed essentially arbitrary. It was therefore decided at this stage to limit our analysis to those papers whose citation history appeared complete – i.e., which were getting almost no further citations by year 15. The specific criteria used was that a paper would be considered still active if it had more than one citation in the last two years or more than two citations in the last three years (as well as more than 15 citations overall).

As can be seen from Table 4, this left only 36 papers in total with 15 or more citations considered to be completed. These were fitted to all four s-curves by minimising the sum of errors across all fourteen points. In looking at the results we should bear in mind the following:

The curves are all characterised by three parameters. The limit relates to the total number of citations – i.e., the Y axis. The scale parameter relates to time – the larger the value the longer the period over which citations occur. The shape parameter relates to spread and skewness or symmetry. The Pearl logistic can only be symmetrical; the Gompertz and gamma can be symmetrical or have positive skew; and the Weibull can also have negative skew.

This sample of papers is obviously not representative of the whole as they have all been completed in a relatively short space of time. Those that are still active will generally be more skewed as their publications carry on.

[3] For papers in management. Papers in some areas of natural science go very much higher.

After fitting, several different patterns of citations could be seen although it should be emphasised that the data generally included a considerable degree of randomness. To illustrate the degree of variety, Figure 5 shows a plot of the scale and shape parameters for the Weibull distribution. The points are also marked according to which function fitted best in ss terms. In terms of the shape parameter, 1 is equivalent to an exponential distribution with strong positive skew and a mode at 0; values around 2-4 are generally symmetrical, while for higher values the distribution becomes very "pointed" and even has negative skew.

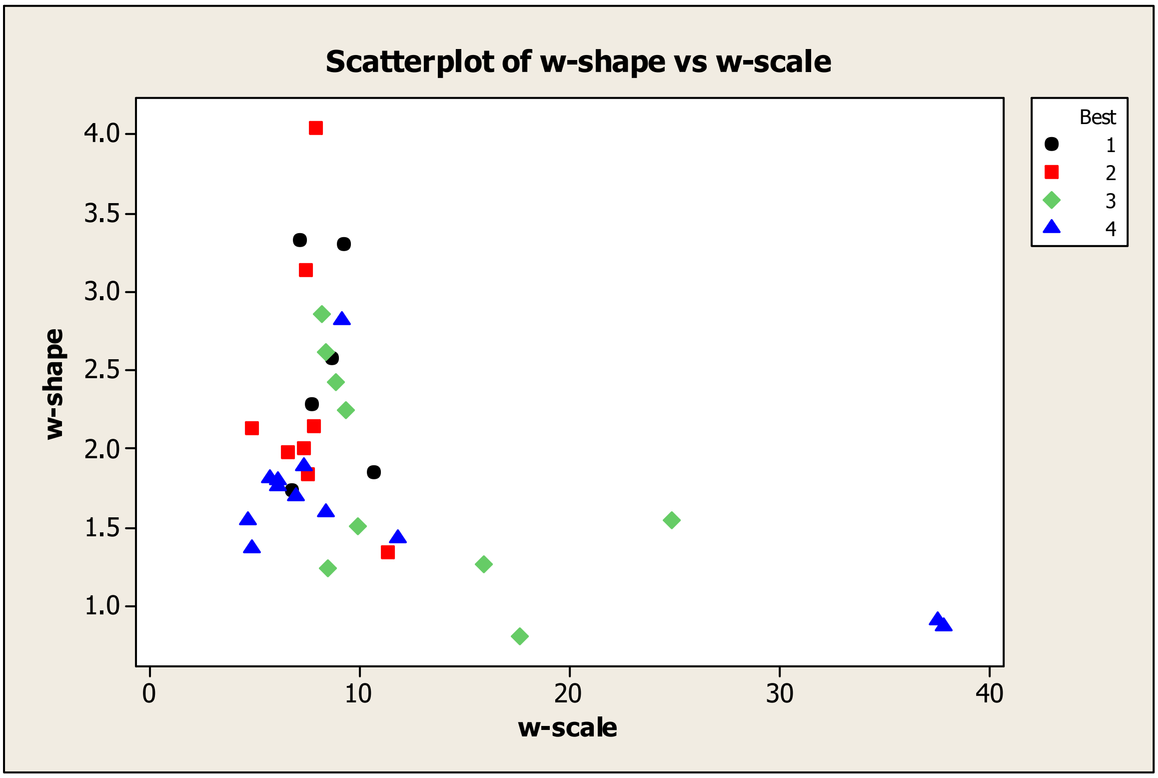

Figure 5 Fitted Weibull parameters for the Completed Papers

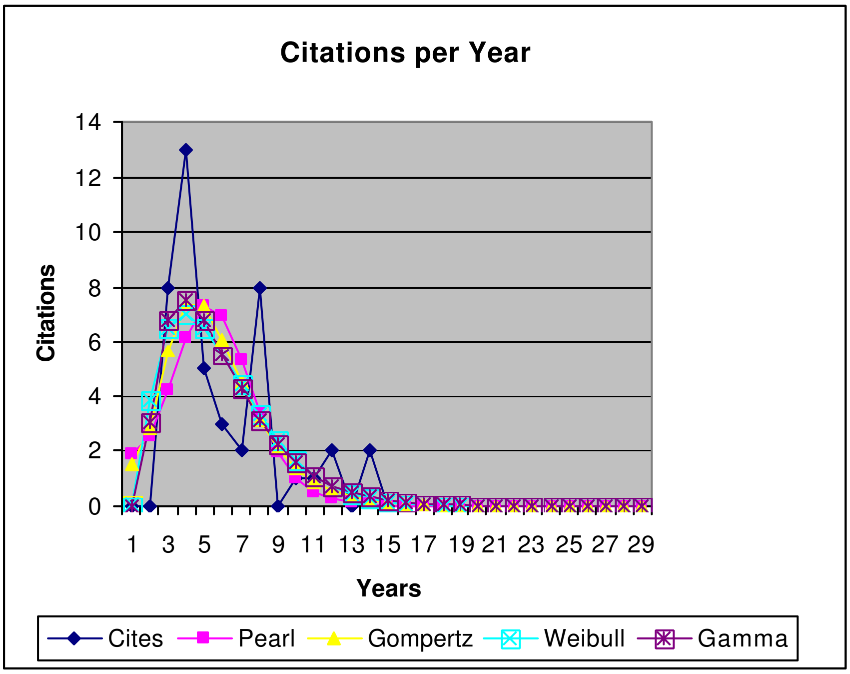
1=Pearl, 2=Gompertz, 3=Weibull, 4=gamma

1. The first group were those which were symmetrical around the point of inflection - the rise and subsequent fall occurred over equal time periods. These were generally fitted best by the Pearl function (6 examples). Series with some positive skew could be fitted with any of the other three functions: Gompertz (8), gamma (5), Weibull (4). Series with a greater degree of skew were best fitted by the Weibull (5) and the gamma (5). Three series had very little pattern with no build up and decline but simply random numbers of citations. These were fitted (poorly) by gamma and Weibull functions with quite extreme parameters. Overall, these results do not support Burrell's (2002) assumption that all papers within a collection will have the same obsolescence function. Having said that, the gamma and Weibull are very flexible and were not that much worse than the Pearl and Gompertz.
2. In terms of shooting stars and sleeping beauties several were identified. Shooting stars will have high initial citations but these will tail off quickly. In one example a paper had acquired 30 cites in four years – 7.5 per year - but only gained another 15 in the remaining ten years

1.5 per year (Figure 6). In terms of the Weibull, such papers would have low values of the scale parameter (<5) with moderate values of shape (1.5 - 3). Two such papers were Wei(4.83,2.13)[4] and Wei(4.69,1.55) which were the two lowest scale parameter values in the sample.

3.



4. Figure 6 A "Shooting Star" (Ref 138)

5. It was harder to find sleeping beauties given the restrictions on the time period of the sample. Van Raan (2004) characterises such papers in terms of the sleeping period (typically between 5 and 10 years), the "depth of sleep" (a "deep sleep" would average no more than 1 citation per year), and the "awake intensity" (average citations after the sleeping period). Such papers would have higher values of the scale parameter (>5) to allow for the sleeping period, together with higher values of the shape parameter (>4). One example is shown in Figure 7 which had only 7 cites in its first six years but then had 14 in its next five. This was fitted as Wei(7.87,4.04). Burrell (2005) provides an interesting analysis of the likelihood of sleeping beauties occurring by chance given an underlying gamma-Poisson production process.

[4] Notationally we use Wei(scale,shape).

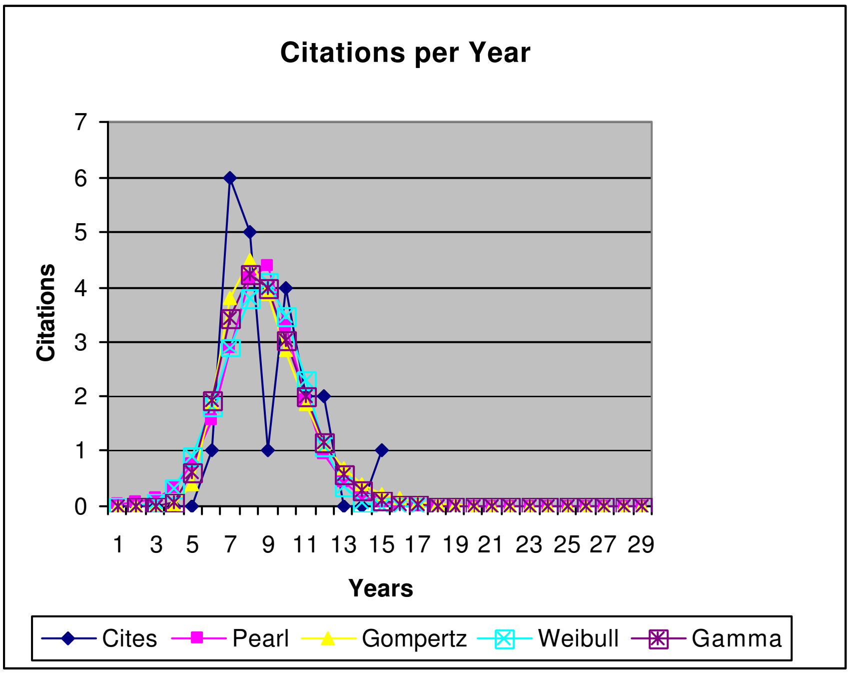


Figure 7 A "Sleeping Beauty" (Ref 249)

6. Finally one pattern emerged that was not anticipated. Of the 36 examples nine had significant dips in the number of citations after 8 or 9 years. This is in fact illustrated in both of the papers in Figures 5 and 6. The dips often went down to zero or one citation before picking up at close to the previous level. This can be seen clearly in Table 5 which shows the total citations for the sample of 36 papers. This rises to a peak of 101 after seven years but then falls suddenly in years 8, 9, and 10 before picking up again. The frequency of occurrence and size of this pattern makes it unlikely to have occurred by chance. The most likely explanation is that initially citations are generated by the first publication of the paper, delayed by the process of writing and getting published the citing paper. Citations then fall off before a second wave emerges triggered by the later citations rather than the original publication. Although, if this is the explanation, it might have been expected to occur earlier, perhaps after five or six years. More detailed work would be needed to test this hypothesis.

Period	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Citations	23	57	83	79	83	94	101	61	69	54	74	43	19	15

Table 5 Total Citations per year for the 36 Completed Papers

3.3 Predicting future numbers of citations

The next research question to be considered was whether it was at all possible to predict the future number of citations for a single paper based on the pattern of citations in the early years?

To begin with only the completed papers were considered for here it was possible to know with some certainty what the actual outcome was. This, of course, is a biased sample with respect to the general population as they will all have completed in a relatively short time and will not have the long positive skew of those still active. The method used was a development of the above whereby the fitting period was varied from five years to the full fourteen years but in each case the SS across the whole series was recorded. This was done for each of the four functions.

The results were, to say the least, highly varied on several dimensions: i) the SS varied hugely depending on the number of fitting periods; ii) it also varied significantly between the different functions, especially initially; but iii) this did not remain consistent as particular functions rose or fell. Figure 8 shows a typical example for one of the papers. In this case, at the start the gamma and Gompertz were best with SS between 200 and 400, while the Pearl logistic was up at 1600. However, within one period the Pearl changed dramatically to become best with less than 200. In period 7 the Gompertz became best and remained so till the end with a final SS of 8. The fit was good from period 10 onwards.

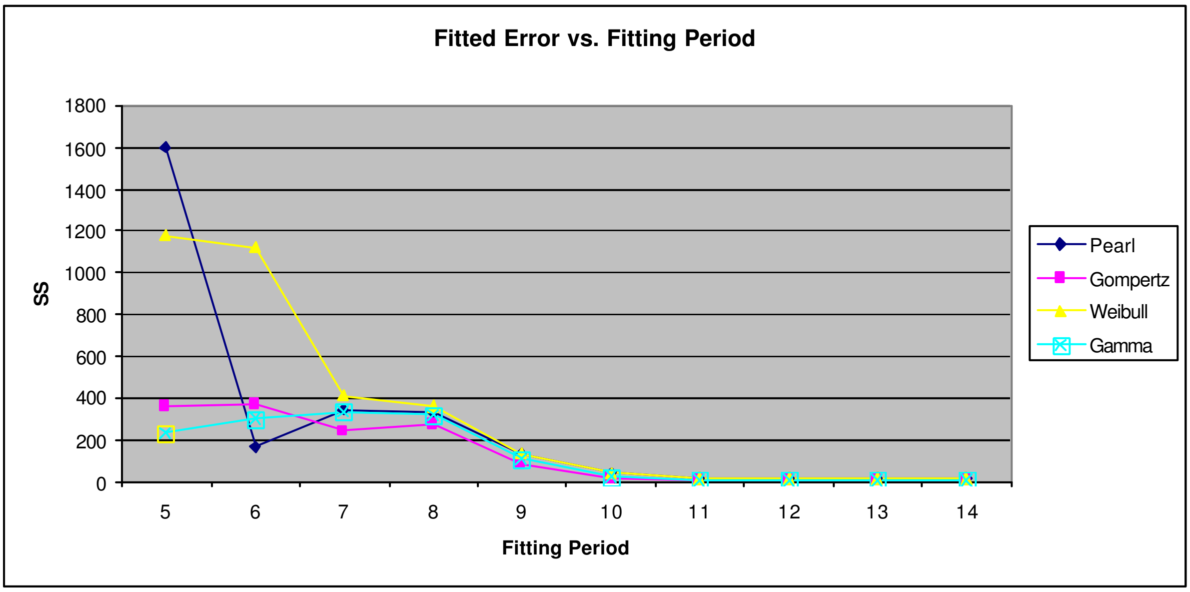

Figure 8 Fitted Errors vs. Fitting Period for Different Functions (paper 249)

Taking firstly the overall quality of fit, we can look at the ratio between the period 5 SS and the period 14 SS as a measure of how much worse the fit becomes with less fitting periods. We can get a lower bound on this by taking the best fitting function at each of the two periods. In practice if we were trying to make predictions ex ante, i.e., without knowing the future citations, results would be worse than this because we would not know which function would turn out to be best. Thus for Figure 8, the best fit SS using all fourteen periods was 7.8, but if only the first five periods were used this rose to 237.9, giving a ratio of 30.5. An alternative approach is to take the 14-period SS as a percentage of the 5-period SS in order to measure the reduction that has occurred. For figure 8 this value is 3.3%. Summary statistics for both these indicators are shown in Table 6.

	SS: Ratio of 5-per. to 14-per.	SS: % 14-per. to 5-per	Years to “reasonable” fit
Min	1.09	0.39%	5
Mean (Mode)	29.05	15.58%	8.9 (10)
Max	256.36	91.76%	12

Table 6 Summary Statistics for SS and Years to Reasonable Fit

Across the papers the mean ratio was 29 times but this rose to as much as 256 times (4633/18) in the worst case. These are very large figures especially given that they are based on the best fitting curve at each period.

At what period, typically, do the fits become reasonable? The term reasonable is somewhat arbitrary but we took the view that when the SS had come down (from on average 29 times) to only being double the final value it was “reasonably” close. In Figure 8, for example, this occurred at year 10. This was recorded for each series and from Table 6 we can see that the mean year at which this occurred was 8.9 with the modal value being year 10. In other words it was only after 10 years worth of data was available for fitting that the SS came to within 100% of the final 14 year value. So the conclusion is that for this data, which is in any case biased in having citation history completed by year 14, the fits are not generally at all reliable before years 9 or 10 by which time there are not many years left.

It had been hypothesised that the time at which the fits became more reliable may be related to the point of inflection of the cumulative curve. Before this point it is difficult to decide when the citations are likely to begin to slow down, but after this point, especially a few years later when the downward slope has become established, on might expect that the fitted curves should settle down. The point of inflection is equivalent to the mode of the corresponding pdf. It is unreliable to estimate this empirically from this data since quite commonly a series may have several modes, i.e., several periods with the same maximum number of citations, so the inflection points were estimated theoretically from the fitted curves given the formulae in Appendix A. The values estimated from the Weibull and gamma parameters were generally extremely similar (r=0.996) and they were also highly correlated with the Pearl and Gompertz (r=0.93)[5] figures. However, it turned out that there was in fact no correlation between the estimated inflection times and the reasonable fitting period as defined above, nor could regression establish a significant relationship.

Looking next at the best fitting function over time, it had been hypothesised that several patterns might occur. For example, that certain functions would predominate in the early periods (e.g., the Pearl/Gompertz because of their relative symmetry) and different ones later on; that the best fitting function would remain fairly constant over the periods; or that the Weibull/gamma functions would predominate because of their flexibility. In the event none of these were observed. There were no cases where the same function remained best throughout the period and it often changed three or more times. The most common ones in the first period (year 5) were Gompertz (12) and gamma (15) whilst the most common at the end was the gamma (13). In only a third of cases were the first and final ones the same function even accepting changes in between.

[5] After removing four unusual observations where the fitted Weibull and gamma shape parameters were <1 – see Appendix A.

The general conclusions from this section are that it is extremely difficult to predict accurately future citations for an individual paper, at least until it is well through its citation lifetime. And that there are no underlying patterns to the sequence of functions fitted or the levels of errors that are generated.

3.4 Fitting Still Active Papers

Finally, we revisited the problem of fitting papers that were still active. The problems can be illustrated in Figures 9a and 9b which show a fairly typical paper that is still actively cited.

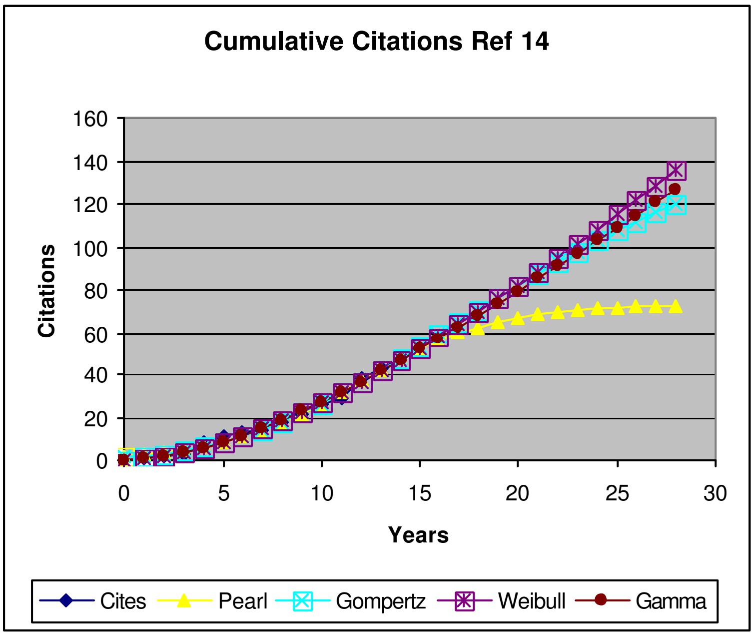

Figure 9a Cumulative Citations and Fitted Curves

In Figure 9a the cumulative s-curve seems well-behaved and appears well-fitted by the curves. It is noticeable that the Pearl-logistic gives a much lower limit than the other three. However, the situation is shown more clearly when we look at the year-on-year citations shown in Figure 9b.

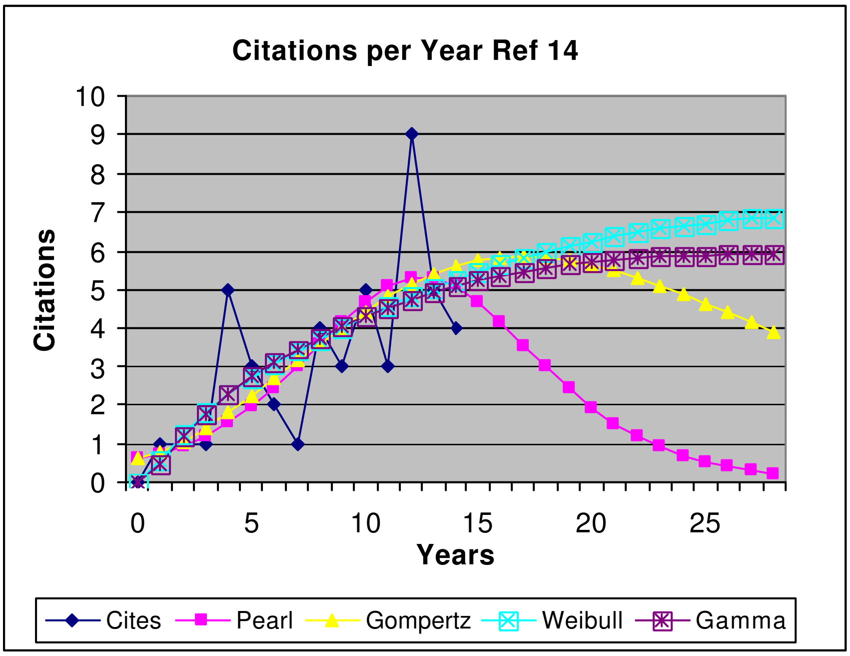

Figure 9b Year-on-Year Citations (equivalent to a pdf)

We can see that citations rose to a peak in year 4 before falling away to year 7. At this point it would have appeared that the citations were ending but they then pick up significantly reaching another peak in year 12. This dip is common and was discussed above. The next two years then fall off again. The question is, what happens next? A further fall would suggest that the point of inflection had passed but it seems equally possible, given the variability of the series, that there could be a rise.

This uncertainty is reflected in the curves that have been fitted. The Pearl, which is symmetrical, turns over and gives the lowest forecast limit of 73. It is always the case with the Pearl on still-active data that it treats the latest peak as the inflection point. The Gompertz gives considerably higher forecasts with a limit of 168. Again its shape is quite constrained. The Weibull and gamma suggest that the citations will carry on rising far into the future and estimate absurd upper limits of 6800 and 4500 respectively. As it turned out, the actual number of citations in the next year (2005) was only one! Whilst this example would appear to strongly favour the Pearl or Gompertz curves, other examples can be found where they significantly under-estimate future citations, even when the inflection point has clearly been reached.

The difficulty of predicting future citations demonstrated by this example reflects very well Meade and Islam's (1998, p. 1116) comments about technological forecasting using s-curves:

> "{i}t is easy to see how difficult it is to recognise that the point of inflection has been reached. It is even more difficult to predict the future path of the curve. The super-imposition of random noise, the case in practice, serves to make the task of forecasting … even more demanding."

4. Conclusions

This paper set out to answer three questions concerning the behaviour of citations: i) to what extent can the citations from collections of papers be modelled by the same obsolescence function? ii) Can we identify different patterns of citation behaviour and explain them? And, iii) can we predict the number of future citations given the pattern of citations in the first few years?

Looking at citations for collections of papers, the significant lack of symmetry over time meant that they were best fitted by the gamma distribution, and occasionally the Weibull, but not the Pearl logistic or Gompertz curves. This confirms earlier research. The fitted parameters were significantly different between journals reflecting the large disparity in the numbers of citations received.

The Move to individual papers brought in a large amount of randomness and variability. Initially analysis concentrated on papers that had generally completed their citations lives to avoid the problems of having to estimate the upper limits to numbers of citations. Here the results were mixed. The gamma and Weibull were best for a majority of papers but the Pearl and Gompertz were best for those which were more symmetrical. This is perhaps surprising as the gamma and Weibull are also capable of taking on symmetrical shapes. This does mean that Burrell's assumption about homogeneity of the obsolescence function is not borne out.

Several patterns were observed in the data including sleeping beauties and shooting stars, and these can be identified through the fitted parameters. An unexpected, but very common, pattern was also observed – that is a dip in citations after 8 or 9 years. This may be due to a shift from citations based on the original paper to those based on other citations but this needs further investigation.

Predicting future citations for individual papers proved to be extremely difficult. For papers whose citations were complete (within the 14 years) the fit became reasonable only after about 10 years, well past the point of inflection. For papers which were still active (the majority) different curves generated wildly different estimates of the potential upper limits.

Finally, it was surprising how many papers were still being actively cited after 14 years. It would be useful to replicate this analysis on a sample that is as old as possible – in the case of ISI data this would be back to 1975

Appendix A: S-Curves Used in the Study

The Logistic Curve (Pearl-Reed curve)

Probably the most widely known growth curve, it was developed originally by Verhulst in 1838 and then popularised by geographers Pearl and Reed (1920). The underlying assumption is that initially the rate of growth is proportional to the size of the population, but that as size increases environmental restrictions will reduce growth until saturation is reached. The derivation and various formulations are explained in Stone (1978).

Equation:

$$Y_t = \frac{L}{(1 + ae^{-bt})} \qquad (1)$$

Parameters

L: upper limit
a: scale parameter affecting the location of the curve
b: shape parameter affecting the steepness/shape of the curve

Note that a and b are independent in that changes in location do not affect the shape.

Characteristics.

The curve is symmetrical about its point of inflection which corresponds to the maximum growth rate. This occurs at $Y = L/2$ when $t = \ln(a)/b$

The growth rate is given by:

$$Y' = bY\left(\frac{L - Y}{L}\right) \qquad (1a)$$

Which shows that the growth at any point depends both on distance to go (L – Y) and distance travelled (Y).

And the proportionate growth by;

$$\frac{Y'}{Y} = b\left(\frac{L - Y}{L}\right) \qquad (1b)$$

Which shows that the proportionate growth is a linear function of the growth so far.

Gompertz Curve

This curve was first formulated by Gompertz in 1825 and differs from the logistic in not being symmetrical about the point of inflection.

Equation

$$Y_t = Le^{-ae^{-bt}} \qquad (2)$$

Parameters

L: upper limit

a: scale parameter affecting the location of the curve
b: shape parameter affecting the steepness/shape of the curve

Characteristics

The inflection point is where $Y = L/e$ when $t = \ln(a)/b$. It thus occurs at the same time as the logistic but the growth value is less - only 73%. Growth is steeper before the inflection point than after it.

The growth rate is given by:

$$Y' = bY\ln\left(\frac{L}{Y}\right) \qquad (2a)$$

Which, for large Y, can be approximated by $Y' = b(L-Y)$ showing that for later periods growth depends only on distance to go to the upper limit, not on previous history.

The proportionate growth is:

$$\frac{Y'}{Y} = b\ln\left(\frac{L}{Y}\right) \qquad (2b)$$

showing that proportionate growth is not linear but reduces as Y approaches the limit.

Weibull Distribution

The Weibull is a statistical distribution commonly used in reliability studies. It was suggested that the cumulative probability distribution (CDF) could be used as an s-curve by Sharif and Islam (1980). It is a very flexible distribution whose probability function can take a variety of shapes from right skew through normality to left skew. It is non-symmetric and flexible in Meade and Islam's (1998) terms.

Equation

The Weibull cdf is given by

$$Y_t = L(1 - e^{-(t/a)^b}) \qquad (3)$$

Parameters

L: upper limit
a: scale parameter affecting the location of the curve
b: shape parameter affecting the steepness/shape of the curve

Characteristics

The inflection point is when $t = a\left(1 - \frac{1}{b}\right)^{\frac{1}{b}}$, where $Y = L\left(1 - e^{-\left(1-\frac{1}{b}\right)}\right)$. (Note that for b<1 the formula breaks down and t is defined as 0 which is the modal point of the probability distribution) This is in contrast to the previous curves which had constant values of Y.. For the Weibull the value of Y at inflection depends on the parameter value b. This provides a greater degree of flexibility in modelling the point of decline in citations.

The growth rate is given by:

$$Y' = \frac{b}{a}(L-Y)\ln\left(\frac{L}{L-Y}\right)^{1-\frac{1}{b}} \qquad (3a)$$

Which shows that growth depends only on the distance to the upper limit.

The proportionate growth is:

$$\frac{Y'}{Y} = \frac{b}{a}\left(\frac{L-Y}{Y}\right)\ln\left(\frac{L}{L-Y}\right)^{1-\frac{1}{b}}$$

Showing that proportionate growth is non-linear.

Gamma Distribution

Another very flexible probability distribution used extensively in queuing and waiting situations. It is similar to the Weibull in taking a variety of shapes from the exponential to the normal. It is non-symmetric and flexible in Meade and Islam's (1998) terms.

Equation

The gamma cdf is given by:

$$Y_t = L\frac{\gamma(b, t/a)}{\Gamma(b)} \qquad (4)$$

Where ?() is the complete gamma function and ?() is the incomplete gamma function. This is an awkward equation form and it is more usually seen as a pdf:

$$y_t = \frac{a^{-b} t^{b-1} e^{\frac{-t}{a}}}{\Gamma(b)}$$

Parameters

L: upper limit
a: scale parameter affecting the location of the curve
b: shape parameter affecting the steepness/shape of the curve

Characteristics

The inflection point is when $t = a(b-1)$. (For b<1 the value is defined to be 0). This corresponds to a Y value of $Y_t = L\frac{\gamma(b, b-1)}{\Gamma(b)}$ but because of the nature of the cumulative gamma function there is no easy expression for this value. It can be calculated numerically. As with the Weibull, the value of Y at inflection depends on the parameter value b. It is also difficult to formulate expressions for the growth rate.
