# Warranty claim forecasting based on weighted maximum likelihood estimation

Artur Akbarov, Shaomin Wu\*

*School of Applied Sciences, Cranfield University, Bedfordshire MK43 0AL, UK*

---

## Abstract

Warranty claims reported in recent months might carry more up-to-date information than those reported in earlier months. Using weighted maximum likelihood estimation for estimating model parameters might therefore lead to better performance of warranty forecasting models than maximum likelihood estimation. This paper examines this issue and also presents comparison of the forecasting performance of the parametric models such as Poisson processes and ARIMA models and non-parametric models such as artificial neural networks. It shows that mixed non-homogenous Poisson process models can lead to better forecasting results than other competing methods. The paper also shows that the models built with the weighted maximum likelihood estimation yield smaller error than those based on the maximum likelihood estimation.

**Keywords:** Warranty forecasting, Poisson processes, weighted maximum likelihood method, overdispersion.

## 1 Introduction

Warranty claim forecasting is becoming increasingly important for businesses as the financial resources associated with warranty coverage are running into millions of pounds. Warranty has become a marketing tool that is utilised to assure the customer of a superior reliability of the product and the manufacturer's commitment to post sale product service. As a result, many manufacturers offer longer warranty, which leads to larger warranty reserves

24 and requires a better resource management through a thorough analysis of warranty data.  
25 This study presents some results on improving the accuracy of forecasting warranty claims.

26 Approaches to warranty data analysis have been addressed by many researchers. For  
27 example, Kalbfleisch et al.<sup>1</sup> uses Poisson models to analyse automobile warranty data with  
28 reporting delays, Murthy<sup>2</sup> discusses warranty cost analysis based on usage rate. Lawless and  
29 Kalbfleisch<sup>3</sup>, Kalbfleisch and Lawless<sup>4</sup>, Lawless<sup>5</sup>, and Suzuki et al.<sup>6</sup> discuss different sta-  
30 tistical aspects of warranty data analysis, Fredette and Lawless<sup>7</sup> discusses warranty claims  
31 forecasting, Akbarov and Wu<sup>8</sup> uses Poisson models to analyse warranty claim data of elec-  
32 tronics products with sales delay. Karim and Suzkui<sup>9</sup> and Wu<sup>10</sup> offers reviews of warranty  
33 literature, respectively. Many of these studies use non-homogeneous Poisson processes to  
34 model warranty data. Also, see Blischke et al.<sup>11</sup> for more recent discussion of the issues  
35 related to the analysis of the warranty data.

36 Wasserman<sup>12</sup> presents application of dynamic linear models to predicting warranty claims.  
37 The author compares the Kalman filter method to the simple linear regression method.  
38 Wasserman and Sudjianto<sup>13</sup> presents the results of comparing the forecasting performance  
39 of three different modelling strategies. The methods are compared based on the analysis of  
40 automobile warranty data. The authors consider static predictive models such as ARIMA,  
41 Kalman filter and artificial neural networks. This study has shown that the neural networks  
42 have resulted in the least forecasting error.

43 Some studies on the analysis of the warranty data have reported the phenomenon of  
44 overdispersion. The overdispersion occurs when the variance of the Poisson random variable  
45 is higher than its expectation, where the two should be equal. The phenomenon is thought  
46 to occur due to intrinsic discrepancies in the reliability of individual products, heterogeneity  
47 of users and operating environments. For more details see Kalbfleisch et al.<sup>1</sup>, Kalbfleisch  
48 and Lawless<sup>4</sup>, Fredette and Lawless<sup>7</sup>, and Akbarov and Wu<sup>24</sup>.

49 In this study we consider the application of the following models. Auto-regressive inte-  
50 grated moving average (ARIMA) models as these models are standard models for forecasting  
51 time series. Non-homogenous Poisson process (NHPP) models as these models are commonly  
52 applied to warranty data. Mixed non-homogenous Poisson process (MNHPP) models as  
53 these models are suitable for dealing with overdispersion. Artificial neural networks (ANN)  
54 as these models have recently become a popular method for various purposes including the  
55 time series forecasting. To our knowledge none of the previous studies on warranty data  
56 analysis has looked at comparing Poisson processes against the ARIMA and neural networks  
57 models.

58 Wu and Akbarov<sup>19</sup> have shown that giving higher weights to recent data can lead to  
59 better forecasting results and use non-parametric approaches to building forecasting models.  
60 In this study we consider a similar approach for estimating the parameters of the Poisson  
61 processes. More specifically, we consider the weighted maximum likelihood method. To our  
62 knowledge this has not been considered for forecasting warranty claim data so far. We show  
63 that weighted maximum likelihood method applied to the mixed non-homogenous Poisson  
64 process gives better forecasts than other methods considered here and also better forecasts  
65 than when it is fitted using the maximum likelihood method.

## 66 2 Parametric models

### 67 2.1 Poisson process models

68 This subsection discusses discrete time Poisson processes parametrised by  $\mu_t$ .  $\mu_t$  is the  
69 expectation of the increment of the process at time  $t$  and depends on the type of the process.  
70 As we consider discrete time processes, we define  $r_t$  to be the expected number of warranty  
71 claims per product unit at time  $t$ .  $r_t$  can be derived from a continuous function as  $r_t =$   
72  $\int_t^{t+\Delta} h(x)dx$ , where  $h(x)$  can be a continuous function such the hazard rate function. Since  
73 we consider monthly data we let  $\Delta = 1$ . We also denote by  $N_t$  the number of products in  
74 the market at time  $t$  and  $d_t$  the number of observed warranty claims in month  $t$ .

75 The *non-homogeneous Poisson process* is one of the most common probability models  
76 used to model failure counts of repairable products, see Ascher and Feingold<sup>20</sup>. The NHPP  
77 assumes that upon repair the failure rate of a product is restored to the same level as it was  
78 just before the failure. Such a repair is referred to as a minimal repair. Many products that  
79 are subject to warranty can be thought of as repairable systems. Even in the cases where  
80 some part of the system is replaced by a new component, as a whole, the system can often  
81 still be viewed as repairable. The NHPP has been applied to model warranty data in studies  
82 such as Kalbfleisch et al.<sup>1</sup>, Lawless<sup>5</sup>, Karim et al.<sup>21</sup>, Wang et al.<sup>22</sup>, and Majeske<sup>23</sup>.

83 The mean of the NHPP is a deterministic function of time. In our case, the intensity  
84 function of the NHPP is given by  $\mu_t = N_t r_t$ . The increments of the NHPP are independent  
85 from each other and distributed according to a Poisson distribution with mean  $\mu_t$ .

86 The *mixed non-homogeneous Poisson process* assumes that the intensity function of the  
87 process is subject to random changes from its expected value. For mathematical simplicity,  
88 such random changes are often modelled using a gamma distribution. Let  $\alpha$  be a gamma  
89 random variable with  $E(\alpha) = a/b$  and denote  $M_t = \sum_{i=1}^t \mu_i$ . Then the number of events

90 in interval  $(0, t]$  is a random variable given by  $\alpha M_t$ . The increments of the mixed Poisson  
91 processes are not independent, therefore  $\mu_t$  is given by  $\mu_t = (\alpha | D_{t-1}) N_t r_t$ , where  $D_{t-1}$  is  
92 the data observed prior to  $t$ , for more details, see Fredette and Lawless<sup>7</sup> and Akbarov and  
93 Wu<sup>24</sup>. For simplicity, we consider an MNHPP model, where  $E(\alpha) = 1$ . The application of  
94 MNHPP to automobile warranty data is considered in Fredette and Lawless<sup>7</sup>.

## 95 **2.2 Weighted maximum likelihood estimation**

96 There are several methods that use weighted approach to finding maximum likelihood esti-  
97 mates, namely, local likelihood, relevance weighted likelihood and weighted likelihood. These  
98 methods define the log-likelihood function in terms of a weights function  $w(z)$  as:

$$\ln L(z; x_1, x_2, \dots, x_n) = \sum_{i=1}^n w(z) \ln L(x_i, \Theta), \quad (1)$$

99 where  $x_i$  is the  $i^{\text{th}}$  observation and  $n$  is the total number of observations.

100 The general form of the local likelihood uses a kernel function to concentrate the weights  
101 around some value  $z$  with bandwidth  $h$ ,  $w(z) = K(\frac{x_i - z}{h})$ , for more details refer to Eguchi  
102 and Copas<sup>25</sup>.

103 The relevance weighted likelihood function is the weighted function of likelihoods of  
104 different data sets assumed to have been generated from distributions similar (at least in  
105 some qualitative sense) to the distribution whose parameters are being estimated.  $w(z)$ , in  
106 this case, reflects the degree of similarity, for an example of the use of this approach see Hu  
107 and Zidek<sup>26</sup>.

108 The term weighted likelihood function has been used in many different contexts, which  
109 are discussed in detail in Wang<sup>17</sup>. Often weighted likelihood methods are used for combining  
110 the likelihoods of data from different but somehow similar samples. Asymptotic properties  
111 of such estimates can be found in Wang et al.<sup>27</sup>.

112 In this paper, we focus on weighing the likelihoods of the data samples based on their  
113 temporal distance from the current point in time. A similar approach has been applied by  
114 Wu and Akbarov<sup>19</sup> in the context of warranty claims forecasting using machine learning  
115 techniques such as support vector regression and neural networks. They have shown that  
116 the weighted approach can yield more accurate forecasts.

117 In the context of warranty claims forecasting, the necessity for weighing the observed data  
118 based on their temporal distances from the current point in time can arise due to the following  
119 reasons. It is often happens that product lines undergo some design or other subtle changes

120 to remove problems identified from the failure of earlier production batches. This makes  
 121 the earlier data less representative of the current failure tendencies. This is one of the most  
 122 common reasons why more recent data plays a more important role for forecasting future  
 123 warranty claims. Also, fast paced technological advances can lead to quick obsolescence of  
 124 products which would have an impact on the propensity of customers to claim warranty due  
 125 to a more preferable option of purchasing a new, more technologically advanced product.

126 In this study we consider the weights function,  $w_t$ , for discrete time series, given by a  
 127 normalised cumulative distribution function of the geometric distribution:

$$w_t = \frac{1}{c}(1 - (1 - \theta)^t), \quad (2)$$

128 where the normalising constant  $c = \sum_{t=1}^T (1 - (1 - \theta)^t)$  with  $T$  being the most recent month,  
 129 and parameter  $p > 0$ , which controls the spread of weights. For example  $\theta = 1$  leads to  
 130 equal weights for all  $t$ . In general, larger values of  $\theta$  lead to relatively more equal wights  
 131 for longer time lags, whereas smaller values of  $\theta$  lead to more variable weights, see Figure 1.  
 132 The choice of the above function implies that the weights are in a strictly increasing order  
 133 from month 1 to month  $T$  and  $\sum_{t=1}^T w_t = 1$ . It also insures that there is no over-reliance on  
 134 the most recent data, where the most recent values have high weights and the rest have very  
 135 small weights. In this study we choose the parameter  $\theta$  that maximises the log-likelihood  
 136 function.

137 The weighted log-likelihood function of the non-homogenous Poisson process is given by:

$$\ln L = \sum_{t=1}^T w_t \{d_t \ln(N_t r_t) - N_t r_t + \ln(d_t!)\}, \quad (3)$$

138 where  $N_t r_t$  is the expected number of claims in month  $t$  and  $d_t$  is the number of observed  
 139 claims in month  $t$ .

140 The weighted log-likelihood function of the mixed non-homogenous Poisson process is  
 141 given by:

$$\begin{aligned} \ln L = \sum_{t=1}^T w_t \{ & \ln(\Gamma(a + A_t + d_t)) + (a + A_t) \ln(b + B_t) + d_t \ln(N_t r_t) \\ & - \ln(\Gamma(a + A)) - (a + A_t + d_t) \ln(b + B_t + N_t r_t) - \ln(d_t!) \}, \end{aligned} \quad (4)$$

142 where  $A_t = \sum_{i=1}^{t-1} d_i$  and  $B_t = \sum_{i=1}^{t-1} N_t r_t$ , see Akbarov and Wu<sup>24</sup>.

Figure 1: Weights function,  $w_t$ , given in continuous form to emphasise the shape of the function.

### 143 2.3 ARIMA models

144 The auto-regressive integrated moving average model (ARIMA) is a widely used time series  
 145 model (see Montgomery<sup>28</sup> and Chatfield<sup>29</sup>, for example). The ARMA  $(p, q)$  model for time  
 146 series  $X_t$  with  $t = 1, 2, \dots$  is given by

$$X_t = \sum_{i=1}^p \beta_i X_{t-i} + \sum_{j=0}^q \gamma_j \epsilon_{t-j} \quad (5)$$

147 where the first term is the auto-regressive model (AR) of order  $p$  and the second term is the  
 148 moving average model (MA) of order  $q$  and  $\gamma_0 = 1$ . When the  $d^{\text{th}}$  difference of a time series  
 149 follows an ARMA $(p, q)$ , the model becomes an ARIMA $(p, q, d)$ . The process can be given a  
 150 mean by adding some constant  $c$  to the above equation.

151 In this paper, the time series under consideration is  $d_t$ . The order terms of the models,  
 152  $p, q$  and  $d$  are determined on the basis of the Akaike information criterion (AIC).

### 153 3 Neural networks

154 Neural networks have become a popular method applied to a wide range of problems such as  
155 function fitting, classification, regression and time series forecasting, the reader is referred to  
156 Bishop<sup>30</sup> for detailed discussion of neural networks. The credibility of the neural networks has  
157 been established by the universal approximation property (Hornik et al.<sup>31</sup> and Funuhashi<sup>32</sup>).

158 Here, we consider a neural network model, or called *multilayer perceptron* (MLP), which  
159 is a feedforward artificial neural network model that maps sets of input data onto a set of  
160 appropriate output. The time series forecasting problem can be formulated as follows:

$$\hat{x}_{t+i} = f(x_{t-K+i}, x_{t-K+i-1}, \dots, x_{t-K+i-p}), \quad (6)$$

161 where  $\hat{x}_{t+i}$  is the forecast for time  $t+i$ , for  $i = 1, 2, \dots, K$ , and  $p$  is the order of auto-regression.

162 The number,  $H$ , of hidden nodes, controls the complexity of the network. A complex  
163 model with a large number of nodes can lead to over-fitting, which means the model performs  
164 exceptionally well on the training set but has very poor generalisation on the test data.

165 Here, we consider two forecasting horizons,  $K = 3$ , and  $K = 6$ . The available data  
166 consists of 24 months of observations for eight products. We use the first 18 months of the  
167 data to fit the models and the remaining 3 and 6 months to test the forecasting accuracy of  
168 the models. The first 18 months of the data are divided into two parts: the first 15 months  
169 are used to train the neural network and the last 3 months, from 16 to 18 are used as the  
170 validation set. The model that results in the lowest error on the validation set is then used  
171 for forecasting purposes.

172 The auto-regression order  $p$  and the number  $H$  of neurons in the hidden layer are chosen  
173 in a way that gives the least error on the validation set.  $H$  is sought in the range of 2 to  
174 7 neurons, and the range of  $p$  is chosen accordingly depending on  $K$ . Since training neural  
175 networks can results in local optima, the network training is performed 30 times for each  
176 combination of  $H$  and  $p$ .

### 177 4 Case study

178 This section presents the results of data experiments using a data set from electronics in-  
179 dustry consisting of eight different products. We use the first 18 months of the data to fit  
180 the models and then measure the forecasting accuracy based on forecasts of 3 and 6 months  
181 ahead.

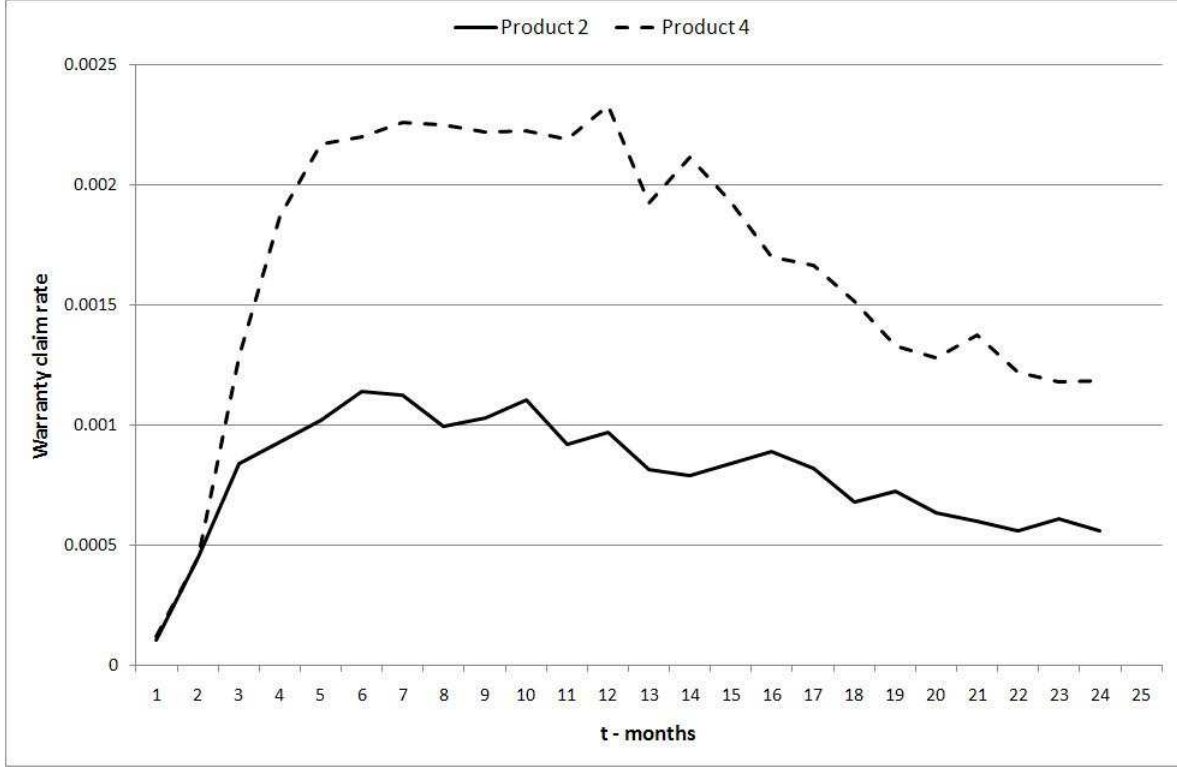

Figure 2: Claim rates for Products 2 and 4.

182 The data set consists of two main pieces of information, the number of products in the  
 183 market in month  $t$ ,  $N_t$ , and the number of warranty claims in month  $t$ ,  $d_t$ . The observed  
 184 claim rate  $r_t$  estimated as  $d_t/N_t$  for two different products is shown in Figure 2. The figure  
 185 shows that the claim rates have a single mode, where after initial increase the claim rate  
 186 start decreasing with time. Other products considered in this study also exhibit a similar  
 187 behaviour, which can be modelled using the hazard rate function of the inverse-Weibull  
 188 distribution given by:

$$h(t) = \alpha\beta^\alpha t^{-(\alpha+1)} e^{-(\frac{\beta}{t})^\alpha} (1 - e^{-(\frac{\beta}{t})^\alpha})^{-1}. \quad (7)$$

189 Thus, the expected number of warranty claims per product unit in month  $t$  is given by  
 190  $r_t = \int_{t-1}^t h(x)dx$  for  $t = 1, 2, \dots$

191 The forecasting error is measured using the normalised rooted mean squared error (NRMSE)  
 192 given by:

$$NRMSE = \sqrt{\frac{\sum_{t=T+1}^{T+K} (d_t - \hat{d}_t)^2}{\sum_{t=T+1}^{T+K} d_t^2}}, \quad (8)$$

193 where  $\hat{d}_t$  is the forecasted value of  $d_t$ ,  $T$  is the number of months used for fitting the models,  
 194 and  $K$  is the forecasting horizon.

195 Table 1 and Table 2 show the results of measuring the forecasting accuracy for all eight

196 products. We can note from these two tables that the MNHPP and the weighted MNHPP  
 197 have the lowest NRMSE for both forecasting periods. Also, we can note that the weighted  
 198 MNHPP and the weighted NHPP have better forecasting accuracy than the MNHPP and  
 199 NHPP respectively.

200 Table 3 shows the results of the paired two-sample test for means between different models  
 201 across all eight products for  $K = 3$ , and Table 4 shows similar results for  $K = 6$ . The tables  
 202 should read as comparing the rows to columns, so the positive sign of the t statistic indicates  
 203 that the mean of the method given in the row is higher than the mean of the method given  
 204 in the column. The values in the parenthesis represent the associated significance values.

205 From both tables, 3 and 4, we can note that the difference between weighted MNHPP,  
 206 NHPP and their counterparts is statistically significant. So, we can conclude that the use of  
 207 weighted maximum likelihood method can give better forecasting results.

208 The wMNHPP column in Table 3 shows that the average of the forecasting error is  
 209 statistically significantly lower than for other methods except for the ARIMA method. Nev-  
 210 ertheless, even compared to the ARIMA method the average of the wMNHPP method is  
 211 28% lower.

212 The wMNHPP column in Table 4 shows similar results. In this case, the average of the  
 213 wMNHPP is statistically significantly lower than for all other methods except for the ANN.  
 214 Even for the case of ANN, the difference is just outside the 0.05 significance level. However,  
 215 the wMNHPP average is 51% lower than the average of ANN.

Table 1: Normalised rooted mean squared error for forecasting horizons  $K = 3$  and  $K = 6$ .

## 216 5 Discussion

217 The results of this study show that MNHPP models have the best forecasting performance.  
 218 For short forecasting horizon  $K = 3$  the next best method is the ARIMA models. This is to  
 219 be expected as ARIMA models often perform well for short forecasting horizons. The NHPP  
 220 model has not given good forecasting results, this can be explained by potential presence of  
 221 overdispersion in the data, where the NHPP model becomes rather inadequate. The neural  
 222 networks have not resulted in better forecasts than the ARIMA or MNHPP models. In

223 general, the neural networks are often do not to generalise well on unseen data. Also, neural  
224 networks can have many local optima which can make it difficult to achieve consistent results  
225 on different runs. Here, we have chosen the neural network model that performs best on the  
226 validation set.

227 The MNHPP models are dependent on the choice of the form of the intensity function.  
228 In our examples, we have chosen the inverse-Weibull distribution, because the observed  
229 rate of the products can be adequately modelled by this function. This is often useful, as  
230 companies produce many similar products and we can choose the intensity function form  
231 depending on the observed behaviour of warranty rates for old products. More flexible forms  
232 of the intensity function can be contemplated. The reliance on the similarity between the  
233 new products and older products can lead to good extrapolations. This is especially true for  
234 electronics industry where many products share similar components.

235 The results of this study emphasise the importance of giving higher weights for more  
236 recent data samples when forecasting warranty claims. We have discussed that the reasons  
237 for this are often justified by external factors that can have an impact on the warranty claim  
238 arrival process.

239 The field warranty data often exhibits overdispersion, where the variance of the incre-  
240 ments of the process is higher than its expectation. From the above results we have seen  
241 that models that can deal with overdispersion fit the data better than the non-homogenous  
242 Poisson process, where the variance and the expectation of the increments are equal. In prac-  
243 tise, the overdispersion can be expected to have a dynamic nature. Mixed non-homogenous  
244 Poisson process updates the level of overdispersion as more data becomes available.

## 245 **6 Conclusions**

246 In this study we have focused on forecasting warranty claims using the following methods,  
247 ARIMA, NHPP, MNHPP and neural networks. It is clear from the results that the MNHPP  
248 model has the best forecasting accuracy, and that estimating the parameters of the Poisson  
249 processes with the weighted maximum likelihood method gives better forecasting results  
250 than those with the maximum likelihood method. Based on those warranty claim data we  
251 have collected, we can draw the following conclusions from this study:

- 252 • Weighted maximum likelihood methods using weights depending on the temporal dis-  
253 tance of data samples from the current point in time can yield more accurate forecasts  
254 than those obtained by maximum likelihood method for Poisson processes. Although,

255 this can be conditional on the choice of the weights function and its parameters, a  
256 suitable choice can have a significant positive impact.

- 257 • Mixed non-homogenous Poisson process can often yield better forecasting results than  
258 the non-homogenous Poisson process. This is mainly due to the fact that many field  
259 warranty data exhibit overdispersion.

260 We recommend that, when fitting forecasting models to field warranty data, one should  
261 consider giving more weights to recent data samples and take into account the phenomenon  
262 of overdispersion, which is often present in real life data sets.

## 263 Acknowledgement

264 We are grateful to the anonymous referees for their valuable comments and suggestions that  
265 improved the quality of this paper. This research is supported by Engineering and Physi-  
266 cal Sciences Research Council (EPSRC) of the United Kingdom (EPSRC Grant reference:  
267 EP/G039674/1).
