Abstract

Background
This study analysed the impact on palliative care outcomes of a new specialist palliative care service for patients severely affected by amyotrophic lateral sclerosis (ALS/MND), multiple sclerosis, Parkinson’s disease and related disorders (multiple system atrophy progressive supranuclear palsy, MSA-PSP).

Methods
The design followed the Medical Research Council Framework for the evaluation of complex interventions. A phase II randomised controlled trial (RCT) was undertaken comparing an immediate referral to the service (FT, fast track) to a 16-week wait (standard track (ST), standard best practice) using a parallel arm design. The main outcome measures were Quality of Life (measured with Schedule for the Evaluation of Individual Quality of Life Direct Weight, SEIQoL-DW) and burden of the carers (Caregivers Burden Inventory, CBI), with secondary outcomes of symptoms, psychosocial and spiritual issues.

Results
50 patients severely affected by neurodegenerative conditions and their informal family carers were randomized: 25 FT, 25ST. At baseline (T0) there were no differences between groups. 4 patients died during the follow-up (2 FT, 2 ST) and 2 patients dropped out before the end of the study. After 16 weeks (T1), Ft participants scored significant improvement in the SEIQoL-DW index, pain, dyspnea, sleep disturbance and bowel symptoms.

Conclusions
This exploratory RCT provides evidence that no harm was experienced by SPCS for patients severely affected by neurodegenerative disorders. There was an improvement in quality of life and physical symptoms for neurological patients in palliative care. Caregiver burden was not affected by the service.
Introduction

Palliative care aims at improving quality of life (QoL) of patients and their families facing problems associated with incurable, progressive and life-limiting disease by means of the impeccable assessment and treatment of symptoms and other psycho- logical, social and spiritual issues. Patients affected by progressive neurodegenerative conditions suffer a high burden of symptoms and issues that are often managed by specialist palliative care teams. However, there is a challenge in providing specialist palliative care service (SPCS) for individuals with advanced neurological conditions as there is a great variability in disease trajectories and symptom profiles. This has been considered in the discussion of the provision of palliative and end-of-life care for this patient group, and there is evidence that the suggested triggers for consideration of care may be of help—these being patient request, family request, dysphagia, cognitive decline, dyspnoea, repeated infections (in particular, aspiration pneumonia), weight loss and marked decline in condition.

Although SPCS has been advocated in the care of patients with neurological diseases, there is very little available evidence about the impact of SPCS on the typical palliative care outcomes. Moreover, there is little definitive evidence for the effectiveness of palliative care generally. One review has shown that the evidence for benefit from specialised palliative care is sparse and limited by methodological shortcomings. Carefully planned trials, using a standardized palliative care intervention and measures constructed specifically for this population, are needed. One project—ENABLE 2—did show in a randomised controlled trial (RCT) that QoL and depression were improved by the SPCS in patients with advanced cancer, even though the physical symptoms were not. A literature review suggested that SPCSs provide significant benefits on patients’ pain and other symptoms for patients with advanced cancer.

Within the care of people with neurological conditions, there has been little research, although one study, an RCT using a delayed intervention model, did show that early specialist palliative care did help people with multiple sclerosis (MS). There were positive results for the management of nausea and sleeping problems to some degree, with the effect strongest after initial contact with the clinical service. There was also a positive impact on informal carer well-being and user satisfaction with the service was high among patients with MS, carers and especially other healthcare professionals. No studies were found in the literature exploring the impact of an SPCS for people severely affected by amyotrophic lateral sclerosis/motor neurone disease (ALS/MND), MS or Parkinson’s disease (PD) when considered as a whole group of people with progressive neurological patients (refs. 12 and 13, p.220).

The aim of this project is to investigate if the involvement of SPCS would affect individual QoL of patients severely affected by neurodegenerative conditions and the burden of care of their informal family carers.

Methods

The study adopted a phase 2 pilot RCT using the fast track (FT) versus standard track (ST) design, also called the waiting list study, adapted from a previous study on MS. This allowed comparison of an SPCS and standard care. This paper has been reported in line with the CONSORT guidelines.
Participants

Participants were adults severely affected by ALS/MND, MS or PD. Informal family carers of the patients were also enrolled if they wished. Patients were resident in Turin city or in the metropolitan area as this was the area where the SPCS—Fondazione Assistenza e Ricerca Oncologia (FARO)—is able to provide care. The severity of the disease was defined according to the Gold Standards Framework prognostic indicators specific for the different conditions as shown in table 1—ALS/MND severe disease, MS Expanded Disability Status Scale equal to or greater than 8.5, PD Hoehn and Yahr ≥4. Participants were excluded if the inclusion criteria were not satisfied, if the cognitive state was compromised so that they could not complete the outcome measures (augmentative or alternative communication aids were incentivised where possible) or if consent to participation was refused. If the informal family carer was not available or the patient did not wish their participation, only the patient was enrolled.

Participants were referred to the study by the medical specialists working in the tertiary clinics for the specific neurological disease groups of two main hospitals of Turin. As this was a pilot RCT, no sample size based on the statistical calculation was calculated a priori, and a sample of 50 participants, allocated 25/group, was chosen as it was estimated that this increase in the number of patients could be coped with by the existing palliative care service.

Every week, two patients with the same disease and similar clinical features (eg, both with ALS/MND and receiving non-invasive ventilation) were assessed at baseline (T0), and then randomised one to the FT group and the other to the ST group using a parallel arm design. The randomisation was undertaken by placing two unrecognisable white folders, containing the two patients’ charts, on a secretary’s desk. The secretary was asked to pick up one randomly and this was chosen as the FT patient, the other patient went into the ST group. Patients allocated in the FT group received the SPCS immediately, whereas those allocated in the ST group waited 16 weeks (T1) before receiving the palliative care input. After T1 all the participants could receive the SPCS, if they wished, for as long as necessary. Participants randomised to the ST group had a waiting list of 16 weeks after allocation, and during this period they received the standard care, provided by primary medicine and hospital specialists. Patients were asked to identify their main informal caregiver and to decide whether they could be involved and complete the tools for caregivers.

The SPCS was provided by FARO Foundation, which provided a team, trained and expert in palliative care, comprising a physician, a nurse, a psychologist and a physiotherapist. The team members visit the patients and the family on a regular basis depending on the palliative care needs and issues that are assessed in that assistance. On average, patients are seen at least weekly by a team member and all patients are discussed at a team meeting every 2 weeks. Volunteers are also available if social support is required. The team can assess symptoms, prescribe medications, provide nursing care and physical therapies as well as psychological support and bereavement care. Team members and study personnel could not be blind to participants, as they were involved in their care.

Measures

The outcome measures were applied at T0 (before randomisation) and at T1 (when only the FT group had received the SPCS care). The main outcomes were:

- Patients’ individual QoL measured with the Schedule for the Evaluation of Individual
Quality of Life Direct
Weight (SEIQoL-DW), a validated tool to measure this domain in these patients’ group; Family informal carers’ burden of care measured with the Caregiver Burden Inventory.

The secondary outcome measures were physical, psychological, social and spiritual issues that had particular relevance to this patient group in an earlier qualitative study. A full list of the outcomes and the relative measurement tools is shown in table 2.

Analysis

Analysis was undertaken from the outcome measures at baseline (T0), after 16 weeks (T1) and the difference between the mean scores (T1−T0). In order to appraise the potential benefit of the SPCS, clinical and statistical significance were considered. The SPSS 15 software package was used for data analysis.

Clinical significance provides information on whether a treatment is effective enough to change a patient’s diagnostic label or to make a significant change in a patient’s condition. For pain and sleep disturbance, this change has been described as greater than 13% and 10%, respectively. It has been suggested that a change of 50% of the SD of any QoL tool can be considered a clinically significant change. This translates to a change of 8–10 points on a 100-points scale.

The clinical interpretation of the results in this study has been categorised in three possible groups:

- No clinical significance if the difference between T1 and T0 is lower than 10% of the scale used to measure that domain;
- Moderate clinical significance if that difference is between 10–19% of the same scale;
- Relevant clinical significance when the difference is 20% or higher.

The statistical analysis included:

- Descriptive statistics to evaluate the comparability of the two study groups
- Group comparison test to detect differences between the two study groups that can be caused by the intervention.
- The aim of this procedure is to determine the efficacy analysis. Depending on the characteristics of the variables, the analysis of covariance (ANCOVA), independent t test or χ² test were used to highlight statistical changes between the two groups.
- The null hypothesis of this study is that no changes are found between the FT and ST groups after the intervention represented by the provision of the SPCS in the treated group versus the best standard care in the control group.
- The α value, determining the statistical significance found in this study, is set at 0.05. Bonferroni adjustments were applied for the ANCOVA test of the variables which were significantly different between the groups at T1.

Ethics

As there was no existing service for people with progressive neurological disease, it was felt to be ethical to delay the service for 16 weeks for the control group, who were offered care at the end of this period. Patients in the control group who experienced symptoms at baseline were advised to consult their general practitioner or neurologist for advice.
Ethical approval was obtained from the Ethics Committee of the two hospitals—Department of Neuroscience, University of Torino and S. Luigi Gonzaga Hospital, Orbassano—and the University of Kent Ethics Committee, University of Kent at Canterbury, UK, as this study was part of a Doctoral study there.

**Results**

Demographics, recruitment, attrition, mortality

From March 2008 to February 2009, 52 potential participants were referred to the study. Two participants refused to participate, both with MS: one did not feel seriously ill and for this reason did not want to be cared for by an SPCS; the other had recently been diagnosed with breast cancer and was going to start chemotherapy. Of the 50 patients enrolled, 30 (60%) were male and 20 (40%) female. The mean age was 61 years and 8 (16%) were aged under 44 years, 17 (34%) 45–65 years and 25 (50%) over 65 years. The diagnosis was ALS/MND for 16 (32%), MS for 18 (36%) and PD for 16 (32%).

Five patients did not wish their carer to be involved, and so 45 family carers were included in the study—24 wives, 12 husbands, 4 daughters, 1 son, 1 mother and 1 sister.

Two patients were not able to complete the SeiQol-DW interview, and therefore their QoL index at baseline is missing. All patients were able to complete the assessment of symptoms. All participants but two completed the psychosocial and spiritual assessment.

At baseline, no differences were found in the two groups for demographics, clinical features, disability level (see online supplementary appendix table S1) and the outcome measure (see online supplementary appendix table S2), showing that the randomisation was successful.

At T1, after FT had received the SPCS, the mortality in the two groups was the same: 2 patients died in the FT group and 2 in the ST group, during the 16 weeks. Two patients dropped out, both in the FT group: a patient with ALS/MND and a patient with MS, both of whom decided not to continue the study for personal reasons after the baseline assessment.

Results of intervention

Outcome measures at T1 revealed a significant improvement (p<0.05) for the FT group in one main outcome, the individual QoL of patients, and in five secondary outcomes, all in the physical symptoms: pain, breathlessness, sleep disturbance, intestinal and urinary symptoms and mouth discomfort—(see online supplementary appendix table S3).

**Clinical significance:** In order to compare the results between the two groups that could be caused by the intervention of the SPCS, new variables were created by subtracting the mean results of the test at T0 (baseline) from the ones obtained at T1 (after intervention). These new variables were called ‘difference variables’ and results are shown in table 3. The difference reported in percentage was used to assess the clinical significance of the results. These results showed a clinical (>20%) improvement of the QoL, pain control, breathlessness and sleep disturbance of the patients who received the SPCS.
**Statistical significance**: A one-way ANCOVA between-groups analysis was conducted for those variables that showed a statistically significant difference between the two groups after the intervention (T1). The aim of this test was to determine whether by adjusting these results for the covariate represented by the baseline assessment (T0) of the same domains the statistical significance was maintained. The seven variables with these characteristics were: QoL and the physical symptoms (pain control, breathlessness, sleep disorders, urinary symptoms, intestinal symptoms and oral symptoms). The independent variable was the type of intervention: FT/ST. The dependent variable was the score on the SEIQoL-DW and the Numerical Rating Scale scores for the remaining six symptoms at T1. Participants’ scores at T0 (baseline) were used as the covariate in this analysis. A Bonferroni adjustment was applied to the α value that was considered significant at 0.007.

As shown in table 4, a statistically significant advantage for FT was shown for the QoL, pain, breathlessness, sleep disturbance and bowel symptoms. Figure 2 (loaded as a separate file) provides an overall picture of the results.

**Discussion**

This study aimed to understand the impact of an SPCS on palliative care outcomes of people severely affected by neurodegenerative disorders. The main outcomes were the individual QoL of patients and the burden of care of their informal family carer. The results show that there was a positive improvement in QoL for those patients who received the SPCS. The overall QoL was similar to that shown in previous studies as in this study the mean SEIQoL-DW was 62, similar to 72, 22 73 31 for ALS/ MND and 61 for MS 21 and 60 for a general palliative care population, 32 although these results are from a single observation and not over time. In this RCT, the sample of patients who received the SPCS scored over 20% higher on the SEIQoL index than the control group, and this difference was confirmed statistically.

The other main outcome on the burden of care for families and carers was not found to be affected by the provision of the SPCS. This may reflect the long disease progression and that families had experienced the burden of caring for the patient for many months or years before the SPCS was provided. Moreover, as the SPCS became involved in these later stages, families were confronted with discussion of death and dying, as the patients were so ill. This may have been difficult for them, so that may have felt that the SPCS added to their psychological burdens.

However, symptoms were shown to be significantly improved, both clinically and statistically, for pain, breathlessness, sleep disturbance and bowel symptoms. It is likely that these improvements had a positive impact on the QoL, and therefore can explain the positive impact of the service on patients’ QoL. The study on patients with MS 11 showed a significant change only in the management of nausea, although there is much anecdotal evidence that SPCS does improve symptom management. 33

There were positive trends towards improvement of other symptoms and issues, in particular social isolation of the patients, all the other physical symptoms, service satisfaction for both patients and informal family carers, and a help to find a meaning in the experience of the disease. Only for the psychological outcomes was the trend towards a worsening in the treated group, although this was not clinically or statistically significant. It is possible that the impact of professionals so used to death and dying caused difficulties in coping with patients who often think themselves as chronically ill, rather than terminally ill. Other studies have suggested
that people with ALS/ MND and other chronic, progressive illnesses may become demoralised and less able to accept changes and work on the more complex and difficult psycho- logical issues.34

The study also showed that recruitment was possible for an RCT of this nature as only two potential participants refused to be enrolled and attrition was low with only two patients abandoning the study. The mortality was equal in the two arms. This was shown in the previous study on MS and shows that palliative care does not seem to hasten death.15 Thus, it would appear that the methodology of the waiting list procedure is feasible and reliable and can be used to assess palliative care outcomes in palliative care settings for patients with an expected life span of months/years. Low attrition and relatively low missing data confirmed a good impact of the study on the participants who adhered to this study and remained in the protocol for the follow-up with a very low attrition rate.

There are limitations in this study as the population was heterogeneous and formed by patients affected by different clinical conditions and with different trajectories. Some tools were not validated for secondary outcomes, but were chosen to measure specific issues that emerged in a previous needs assessment.35 Only one evaluation and no crossover could be carried out over time, so we do not know if the improvement in the measured domains is maintained. Within the practicality of this study, these issues could not be addressed but ideally should have been considered.

Conclusion

This study represents one of the first published experiences of assessment and evaluation of the impact of an SPCS in non-cancer conditions. Moreover, there are very limited assessments of any palliative care in any patients group, although there has been evidence of early palliative care leading to improved QoL and prognosis in lung cancer.36 The lack of evidence of effect on informal carers’ well-being should be studied in depth. The approach to relatives who have been providing care to their beloved for a very long time could be different from that successfully adopted to support informal carers of patients with cancer.

Table 1 – Clinical requirements indicating advanced disease

General indicators of deterioration in neurological diseases
- Progressive deterioration in physical or cognitive function despite optimal therapy
- Complex symptoms
- Swallowing problems leading to respiratory complications
- Speech problems: dysarthria and progressive dysphasia

Specific clinical indicators for the disease groups

**ALS/MND**
- Evidence of disturbed sleep related to respiratory muscle weakness in addition to signs of dyspnoea at rest
  - Increased cognitive difficulties/barely intelligible speech
  - Difficulty swallowing poor nutritional status/weight loss
  - Needing assistance with ADLs
  - Medical complications, eg, pneumonia, sepsis
  - A low vital capacity (below 50% of predicted, hypercapnia)

**Multiple sclerosis**
1. EDSS ≥8, 5
2. Presence of at least one of the following conditions:
   - Significant complex symptoms and medical complications
   - Dysphagia (swallowing difficulties) admissions with sepsis and poor nutritional status
   - Communication difficulties, eg, dysarthria+fatigue
   - Cognitive impairment
   - Breathlessness

**Movement disorders**
1. Hoehn and Yahr stage ≥4
2. No indication for neurosurgical procedures
3. The presence of 2 or more of the following criteria:
   - Drug treatment is less effective or an increasingly complex regime of drug treatments
   - Reduced independence, need for help with daily living
   - Recognition that the condition has become less controlled and less predictable with “off” periods
   - Dyskinesias, mobility problems and falls
   - Swallowing problems
   - Psychiatric signs (depression, anxiety, hallucinations, psychosis)

Adapted from the Gold Standards Framework prognostic indicator guidance.
ADL, activity of daily living; ALS/MND, amyotrophic lateral sclerosis motor neurone disease.

Clinical significance:

- Δ is the numerical difference in the mean score T1–T0 between the FT and ST groups.
- Δ % is the difference in the percentage of the mean score T1–T0 between the FT and ST groups.
  - ≥20% is considered as a relevant significant difference.
  - 10–19% is considered as a moderate clinical significance.
  - <10% no clinical difference.

*Statistical significance: Significant at p<0.05 level.

</table>

Significant p value at <0.007 (Bonferroni adjustment). F1=ANCOVA test result.
Each 2 weeks 2 potential participants were referred to the SPCS.

**Time 0 (T0)**
- First visit:
  - Consent Letter to the GP
  - First assessment (baseline)
- Randomization in that same week
- Allocation: 1 patient in the FT, 1 patient in the ST

FT: receiving the SPCS
ST: in waiting list
- FT = on charge at the SPCS, seen by the team, palliative care program set up
- ST = no contacts with the SPCS. Still receiving the standard care

**16 weeks**

**Time 1 (T1)**
- Second assessment
- End of the study

Scheme repeated for 25 weeks:
- 50 patients and 50 carers
- 25 FT
- 25 ST

After 16 weeks all participants receive the SPCS free of charge for the required time.

---

Figure 1 Flow chart of the study loaded as a separate file (GP, general practitioner; SPCS, specialist palliative care service; ST, standard track).
Figure 2 Overall results loaded as a separate file (ANCOVA, analysis of covariance; FT, fast track; QoL, quality of life ST, standard track.

Comparison between Δ means T1-T0 (in %) between the FT and ST groups.

- **I** bars represent domains with both a statistical (p<0.007) and clinically relevant (Δ>20%) advantage for FT versus ST.
- **II** bar represents a clinical relevant advantage of FT vs ST, but no statistically significant difference.
- **III** bars represent clinical moderate advantage (Δ 10-19%) for FT vs ST, but no statistically significant difference.
- **IV** bars represent domains where no statistical nor clinical significant differences were found between the groups.
