## ABSTRACT

Existing methods for generating a detailed trace of a computation of a lazy functional program are complex. These complications limit the use of tracing in practice. However, such a detailed trace is desirable for understanding and debugging a lazy functional program. Here we present a lightweight method that instruments a program to generate such a trace, namely the augmented redex trail introduced by the Haskell tracer Hat. The new method is a major step towards an omniscient debugger for real-world Haskell programs.

## CCS CONCEPTS

## 1 INTRODUCTION

A detailed trace of a computation is the basis for any so-called omniscient debugger for a programming language (Zeller 2009). A trace substantially supports the processes of understanding and debugging a program. Today’s computers provide gigabytes of volatile and non-volatile memory. Therefore storing a detailed trace of a substantial part of a computation poses no practical problem. The Big Data challenge for computer science is to define a trace structure, generate it and finally make good use of it. The Haskell tracer Hat defines the augmented redex trail (ART) as a trace structure and comprises tools for generating and using it (Section 9). This paper is about a better method for generating the ART.

Consider the Haskell program in Figure 1. A recogniser determines whether a given word is within a given LL(1) grammar. If

```
type Recogniser = [Char] -> Maybe [Char]

lit :: Char -> Recogniser
lit x [] = Nothing
lit x (y:ys) = if x==y then Just ys else Nothing

(<|>) :: Recogniser -> Recogniser -> Recogniser
(r1 <|> rr) xs = r1 xs `mplus` rr xs

mplus :: Maybe a -> Maybe a -> Maybe a
mplus Nothing mr = mr
mplus ml _ = ml

binaryDigit :: Recogniser
binaryDigit = lit '0' <|> lit '1'

main = print (binaryDigit [])
```

Figure 1: A simple recogniser for words in an LL(1) grammar.

a prefix of the given word is in the grammar, then a recogniser returns `Just xs` with `xs` being the remainder of the input word; otherwise the recogniser returns `Nothing`. Only the combinators necessary for defining the recogniser of a binary digit, which is 0 or 1, are given. Computation starts with evaluating `main`, which applies the recogniser to the empty list. The result is `Nothing`.

Figure 2 shows the ART for our example. An ART is basically the graph produced by a naive implementation, a simple graph rewriting machine, except that a reduction step does not overwrite a redex by a reduct, but instead connects the redex node with a reduction edge to the reduct node. The nodes of an ART are labelled with function and constructor identifiers or are application nodes `App` or indirection nodes `Ind`. For easy referencing we identify every node by a number. There are three sorts of edges:

- A **bold reduction edge** leads horizontally from the root of a redex to the root of its reduct. Starting for example at node 1, the redex `main` reduces to node 2, an application of `print`.
- A normal unbroken edge leads from a node down to one of its components. For example, following all component edges we find that node 2 represents the expression `print (binaryDigit [])`. Similarly node 45 represents the expression `lit _ []`. Here `_` represents an unknown value that lazy evaluation never demanded.
- Every node except for the start node 1: `main` is part of a reduct. A **dotted parent edge** leads from every node to the root of its redex. For example, the parent of 38: `[]` is 1: `main`.

```

**Figure 4: ART of Figure 2 using types of Figure 3.**

and a variable can be the root of a redex and hence they both have a reduction pointer. If there is no reduction, then the reduction pointer is noId. Finally, both applications and indirections can have components. An application can have two components, left and right. At creation time of an application node these components are still unknown and hence are noId. In contrast, for an indirection its component tind is always well-defined. Indirection nodes are needed to ensure that from every reduct its redex can be reached via a parent pointer (Sparud and Runciman 1997a): When an applied function is a projection, an indirection node is added to the ART to represent the result. The parent pointer of the indirection is different from the parent pointer of its component.

Figure 4 shows the ART of our example program using the data types of Figure 3.

## 2.2 Hat's Program Transformation

To generate an ART, the Haskell tracer Hat transforms a Haskell program into another Haskell program that, when executed, has the

same observable behaviour as the original program but in addition writes an ART describing the computation into a file. File writing is mostly sequential, but because the ART is a graph with cycles, some forward pointers in the ART file have to be updated.

To generate all the graph edges of the ART, the transformation inserts in numerous places in the program a pointer of type RefExp. Hence the types of all expressions, including function identifiers, change. Every expression of type T is replaced by an expression of type R T, where

```
data R a = R a RefExp
```

that is, every subexpression is paired with a pointer. Data types change accordingly, for example the definition of the tree type

```
data Tree a = Empty | Node (Tree a) a (Tree a)
```

becomes

```
data Tree a = Empty | Node (R (Tree a)) a (R (Tree a))
```

Every function type is replaced by the new function type

```
newtype Fun a b = Fun (RefExp -> R a -> R b)
```

It is substantial work and difficult to implement Hat's program transformation correctly. Another drawback is that the additional pointers in data structures and function parameters increase the space and time requirements of the program.

## 2.3 The Idea

During program execution we generate a sequence of events. This sequence could be held in memory or be written sequentially to file. Every new event is added to the end of the current sequence; earlier events are never changed. After the execution has terminated, a single traversal of the sequence from beginning to end translates the event sequence into an ART, which contains both backward and forward pointers.<sup>1</sup>

In the next sections we assume that a program is just a sequence of top-level function definitions. In Section 7 we discuss further language constructs such as local definitions and constants.

*2.3.1 "Identity" Functions with Side-Effects.* We can instrument any subexpression  $M$  of a program such that an event is recorded, either just before evaluation of  $M$  or just after evaluation of  $M$ . We just replace  $M$  by `instPre "begin" M`, respectively `instPost "end" M`, where

```

instPre :: String -> a -> a
instPre event exp = unsafePerformIO $ do
  sendEvent event
  return exp

instPost :: String -> a -> a
instPost event exp = unsafePerformIO $ do
  exp `seq` sendEvent event
  return exp

```

Here `sendEvent :: String -> IO a` adds the given string as an event to the end of our global sequence of events. The function `unsafePerformIO :: IO a -> a` turns the event recording into a side-effect, such that `instPre "begin"` and `instPost "end"` are

<sup>1</sup>We assume that a forward pointer in the ART can be updated in constant time. Although we also traverse parts of the already constructed ART, for all practical purposes the translation is linear in the length of the event sequence.

polymorphic functions that do not change the type of their arguments. For the combinator `instPost` it is important that Haskell provides the parametrically polymorphic function `seq :: a -> b -> b` that forces evaluation to weak-head normal form of its first argument before returning its second argument. Therefore `instPre` first sends the event and then evaluates its argument and `postPre` evaluates in the opposite order.

**2.3.2 Event References Record Expression Nesting.** For each function symbol, data constructor and application we will generate an event. To be able to reconstruct whole nested expressions, events have to be able to refer to each other. Each event in our sequence of events can be identified by a unique event identifier; for simplicity we choose as event identifier the position of the event in the sequence, starting with 0. A later event in the sequence can refer to an earlier one by including the event identifier of the earlier one in the later event. Thus we can record an expression having two subexpressions by ensuring that the events for the two subexpressions refer to the event of the whole expression. For example, our transformation can replace  $e_1e_2$  by `app e_1e_2`, where

```
app :: (a -> b) -> a -> b
app f x = unsafePerformIO $ do
  appId <- sendEvent "apply"
  return ((instPre ("left" ++ show appId) f)
          (instPre ("right" ++ show appId) x))
```

Here it does not matter whether we use `instPre` or `instPost`. We also note that eventually we should define a new data type for events instead of encoding them as strings.

We ensure that for every subexpression there is an event with a reference to the event of the surrounding expression. Because we add later events at the end of the sequence and never update earlier events, subexpressions have to refer up to events representing larger expressions, but never vice versa. When translating the event sequence in one linear traversal into an ART we have to invert all references to obtain component edges.

**2.3.3 Delimit Chains of Reduction.** Whenever evaluation of an expression is started, it will be rewritten in a sequence of steps until its value is reached; in terms of ART structure there is a chain of redexes with reduction edges until finally there is a non-redex.<sup>2</sup> Our ART of Figure 2 shows five such chains:

```
1  → 2
7  → 18 → 60
9  → 10
45 → 58
26 → 42
```

We can instrument any subexpression  $M$  of a program such that an event marking the start is recorded before evaluation of the subexpression starts, and another event marking the end is recorded after a value was reached. We just replace  $M$  by `ev M`, where

```
ev :: a -> a
ev = instPre "begin" . instPost "end"
```

<sup>2</sup>We will discuss exceptions, including runtime errors and abortion of a computation by the programmer in Section 7.4.

```
myId :: Bool -> Bool
myId True = True
myId False = False

myNot :: Bool -> Bool
myNot True = myId False
myNot False = myId True

z :: Bool
z = myNot (myNot True)
```

Figure 5: A program with expression nesting.

```
myId :: Bool -> Bool
myId True = instPre "True" True
myId False = instPre "False" False

myNot :: Bool -> Bool
myNot True = instPre "apply myId" (myId False)
myNot False = instPre "apply myId" (myId True)

z :: Bool
z = ev (instPre "apply myNot" (myNot
  (ev (instPre "apply myNot" (myNot True))))
  )
```

Figure 6: Program with some tracing combinators.

Figure 7: Sequence of events generated by evaluation of  $z$ .

*Example.* Figures 5 to 7 demonstrate how chains are recorded. For simplicity here we ignore the nesting of expressions but just record data constructors and function applications. We instrument the program of Figure 5 with the tracing combinators and obtain the program of Figure 6. When evaluating the expression  $z$ , the event sequence of Figure 7 is generated. The markings on the left emphasize that the events `begin` and `end` serve as start and end markers of chains. One chain of reductions is nested within another chain of reductions. The variable  $z$  reduces to an application of `myNot` which reduces to an application of `myId`, which reduces to the data constructor `True`. That reduction chain is interrupted by another reduction chain that shows that an application of `myNot` reduced to an application of `myId`, which reduces to the data constructor `False`.

**2.3.4  $\lambda$ -bound Variables.** One additional idea is required to handle parameter variables such as  $x$  and  $r1$  in the example in Figure 1.

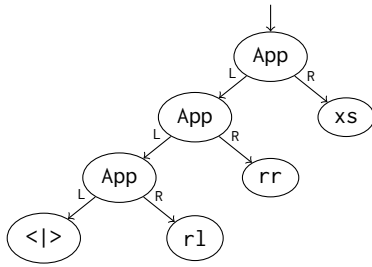

Figure 8: Left side of the equation of `<|>` in Figure 1 as a tree.

As Figure 2 demonstrates, an ART contains nodes for variables such as `lit`, `binaryDigit` and `<|>`, but not for parameter variables.<sup>3</sup> We call the recorded variables *let-bound* and the unrecorded parameter variables  *$\lambda$ -bound*.<sup>4</sup> For example, the program equation

$$(r1 \langle | \rangle rr) \text{ xs} = r1 \text{ xs} \text{ 'mplus' } rr \text{ xs}$$

uses the  $\lambda$ -bound variables `r1`, `rr` and `xs`. The program execution that yields the ART shown in Figure 2 uses the equation exactly once. Rewriting the equation without infix notation and annotating subexpressions with the corresponding node identifiers of the ART shows more clearly how the equation is used:

$$(((\langle | \rangle)^{14} r1)^{12} rr)^{10} \text{ xs})^7 = ((\text{mplus}^{22} (r1 \text{ xs})^{26})^{20} (rr \text{ xs})^{45})^{18}$$

The instrumented right-hand sides of the equations for `main` and `binaryDigit` yield the ART nodes 14, 12, etc. that form the left-hand side of the equation for `<|>`. The instrumented right-hand side of the equation for `<|>` yields the ART nodes 22, 26, 20, etc. for the right-hand side of the equation. However, additionally that instrumented code has to connect the component edges of the `App` nodes 26 and 45 correctly.

We can identify every  $\lambda$ -bound variable of an equation by a list of left or right branches that indicate their location in a syntax tree of the left-hand side, starting at the root node. The left-hand side of the defining equation of `<|>` has the syntax tree shown in Figure 8. The tree yields for each  $\lambda$ -bound variable the following list of branches:

```

xs: [R]
rr: [L,R]
r1: [L,L,R]

```

So each event generated for a  $\lambda$ -bound variable contains such a list. The list enables us to add a component edge: the parent of the  $\lambda$ -bound variable is the root node of the left-hand side in the ART and from there we can follow left and right as the branch list specifies to find the root node of the expression bound to the variable. So to add the component edge in the ART, a small part of the already constructed ART needs to be traversed.

<sup>3</sup>Originally this decision was made because the ART was inspired by term rewriting. A term rewriting sequence (computation) contains function identifiers but all parameter variables have been instantiated by substitution. A later justification of this design decision is that function identifiers are essential for understanding a computation, because in contrast to parameter variables they traditionally have meaningful names. As we want to generate an ART, we follow that decision, although recording also parameter variable identifiers would be trivial to implement.

<sup>4</sup>The naming stems from how a full Haskell program with local definitions in where blocks and class instances would be translated into a core  $\lambda$ -calculus with a *let-binding*.

2.3.5 *Summary.* We instrument every subexpression on the right-hand side of an equation. Thus during program execution we record variable and constructor identifiers, but also expression constructs such as applications. These events yield the nodes of the ART.

- The marker events `begin` and `enter` delimit a chain and enable us to construct the reduction edges of the ART.
- The nesting of chains reflects the evaluation order, not the nesting of expressions in the program. So to construct the component edges of the ART, we add an event reference to the surrounding expression to each `Enter` event. The event for a  $\lambda$ -bound variable has a branch list that enables construction of the component edge.
- Finally the parent edges are actually fully determined by the reduction and component edges: the parent of a node in the middle of a chain is the preceding node of the chain (inverse of a reduction pointer); basically the parent of any other node is the same as the parent of the node that they are a component of (inverse of a component pointer).

### 3 EVENTS AND TRACING COMBINATORS

In the preceding section we discussed our ideas using strings as events and we used simplified tracing combinators. Now we combine these ideas to obtain a working tracing system.

Figure 9 gives the definition of events and related types. Every event in an event sequence has a unique `EventId`, which is its position in the sequence.

The subsequence from an `Enter` event to its corresponding `Value` event, without any nested subsequences, describes a chain of reductions. Thus we can later construct reduction edges. An `Enter` event has an `EventId` and a `Branch`, to specify which component of which node it is. This information enables us later to construct component edges.<sup>5</sup> A constructor event has the name and arity of the constructor, and an event for a *let-bound* variable has the name of the variable. The event for a  $\lambda$ -bound variable has a list of branches as discussed in the preceding section. Finally, there is the application event `App`.

Figure 10 defines the tracing combinators that we use to generate the event sequence. We assume that `sendEvent` is a function that takes an event and adds it to the end of the global event sequence; it also returns the unique `EventId` of that event. The function `runH` initialises the global event sequence, evaluates the given IO-expression, transforms the event sequence into an ART as we will discuss in Section 4 and finally writes the ART to a file with the given name.

The combinator `eval` marks the beginning and end of a chain of reductions as discussed in Section 2.3.3; it just takes an `EventId` and `Branch` as parameters, to include them in the `Enter` event. Combinators `con` and `var` generate constructor and *let-bound* variable events. The combinator `LamVar` generates the event for a  $\lambda$ -bound variable. The definition first forces the evaluation of the variable via `seq`, so that the chain of computation for the variable is recorded in the event sequence before the `LamVar` event is added. Finally the

<sup>5</sup>A component edge of an ART always points to the start of a chain. Considering that most uses of an ART are interested in the end of a chain, it would probably be more efficient to have every component edge point to the end of a chain.

```

type EventId = Int
data Branch = L | R
type Name = String

data Event =
  Enter EventId Branch
  | Value
  | Con Name Arity
  | Var Name
  | LamVar [Branch]
  | App
    
```

Figure 9: Events recorded in a sequence.

```

sendEvent :: Event -> IO EventId

runH :: FilePath -> IO a -> IO ()

eval :: EventId -> Branch -> a -> a
eval parent branch x = unsafePerformIO $ do
  sendEvent (Enter parent branch)
  x `seq` sendEvent Value
  return x

con :: Name -> Arity -> a -> a
con name arity x = unsafePerformIO $ do
  sendEvent (Con name arity)
  return x

var :: Name -> a -> a
var name var = unsafePerformIO $ do
  sendEvent (Var name)
  return var

lamVar :: [Branch] -> a -> a
lamVar pos var = unsafePerformIO $ do
  var `seq` sendEvent (LamVar pos)
  return var

app :: (a -> b) -> a -> b
app f x = unsafePerformIO $ do
  eventId <- sendEvent App
  return ((eval eventId L f) (eval eventId R x))
    
```

Figure 10: Tracing combinators.

combinator `app` records an application event. It wraps the combinator `eval` around both components of the application. This collaboration of the two combinators ensures that the component structure of expressions is recorded in the trace. The combinator `eval` is used only in the definition of `app` and for starting the computation of a complete program in the definition of `runH`. The combinator `app` is the only combinator that uses the unique identifier returned by `sendEvent`.

Figure 11 shows the complete event sequence for our program from the Introduction. The markings on the left emphasise the

Figure 11: Events for the example program in Figure 1.

```

import HatLight
import qualified Prelude
import HatPrelude

type Recogniser = [Char] -> Maybe [Char]

lit :: Char -> Recogniser
lit x [] = con "Nothing" 0 Nothing
lit x (y:ys) =
  app3 (var "if" ifThenElse)
    (app2 (var "==" (==))
      (lamVar [L,R] x) (lamVar [R,L,R] y))
    (app (con "Just" 1 Just) (lamVar [R,R] ys))
    (con "Nothing" 0 Nothing)

    (app (lamVar [L,L,R] r1) (lamVar [R] xs))
    (app (lamVar [L,R] rr) (lamVar [R] xs))

mplus :: Maybe a -> Maybe a -> Maybe a
mplus Nothing mr = lamVar [R] mr
mplus ml _ = lamVar [L,R] ml

binaryDigit :: Recogniser
binaryDigit =
  app2 (var "<|>" (<|>))
    (app (var "lit" lit) (con "'0'" 0 '0'))
    (app (var "lit" lit) (con "'1'" 0 '1'))

main =
  runH "Recogniser" Prelude.$ var "main" Prelude.$
    app (var "print" print)
      (app (var "binaryDigit" binaryDigit)
        (con "[]" 0 []))

```

**Figure 12: Transformed Example Program.**

chains of reductions just as in Figure 7. The whole sequence is bracketed by an Enter 0 L and a Value event that were generated by runH. The additional information of an Enter event determines for a chain to which component of which application it belongs. Every App event is followed directly by an Enter event for its left component, the applied function. An Enter event for its right component, the argument of the function, may appear later in the event sequence, but will only appear if it is demanded.

## 4 PROGRAM TRANSFORMATION

A transformation that inserts the tracing combinators instruments a program for tracing. Figure 12 shows the result of transforming our introductory program of Figure 1. A module import for the tracing library HatLight that defines the tracing combinators is added. The standard library Prelude is hidden and instead a tracing version of it, HatPrelude, is imported. All type definitions and type signatures remain unchanged, just like the left-hand sides of

```

data Chain = Context NodeId Branch | Last NodeId

mkArt :: [Event] -> ART
mkArt es = go es [] 0 Map.empty

go :: [Event] -> [Chain] -> NodeId -> ART -> ART
go (Enter a b : es) cs id art =
  go es (Context a b : cs) (id+1) art
go (Value : es) (c:cs) id art =
  go es cs (id+1) art
go (Con name arity : es) cs id art =
  writeAndGo es cs id
  (\p -> TCon p name arity) art
go (App : es) cs id art =
  writeAndGo es cs id
  (\p -> TApp noId p noId noId) art
go (Var name : es) cs id art =
  writeAndGo es cs id
  (\p -> TVar noId p name) art
go (LamVar d : es) (Context a b : cs) id art =
  go es (Last n : cs) (id+1) (writeArg a b n art)
  where
    n = directionLookup (getParent a art) d art
go (LamVar d : es) cs id art =
  writeAndGo es cs id
  (\p -> TInd p (directionLookup p d art)) art
go [] [] _ art = art

writeAndGo :: [Event] -> [Chain] -> NodeId ->
  (NodeId -> TNode) -> ART -> ART
writeAndGo es (c:cs) id newNode =
  go es (Last id : cs) (id+1) .
  writeConnect c id newNode

writeConnect :: Chain -> NodeId ->
  (NodeId -> TNode) -> ART -> ART
writeConnect (Context a b) id newNode art =
  writeArg a b id .
  Map.insert id (newNode (getParent a art)) $ art
writeConnect (Last l) id newNode art =
  updateReduction l id .
  Map.insert id (newNode l) $ art

```

**Figure 13: Translation of an event sequence into an ART.**

equations that define functions. However, all expressions are transformed by inserting tracing combinators. That transformation is straightforward, except that for each use of a  $\lambda$ -bound variable a list of branches is needed, which is obtained from the left-hand side of the equation as described in the previous section. The combinators  $\text{app}(n)$  are variants of  $\text{app}$  that apply a function to  $n$  arguments. The function  $\text{main}$  uses  $\text{runH}$  and starts by recording its own variable identifier in the event sequence. Executing this program yields the event sequence shown in Figure 11.

## 5 TRANSLATION FROM EVENT SEQUENCE TO ART

When we generate an event sequence, we never update any event; we only join new events at the end. Thus an event sequence has backwards references, namely the `EventId` of each `Enter` event, but no forward references. We translate such an event sequence into an ART which also has forward references, namely the component and reduction pointers. Translation traverses the event sequence once from beginning to end. From each event a new ART node is created, except for `Enter` and `Value` events. For simplicity we use the `EventId` of an event as the `NodeId` of the corresponding ART node. Hence there are no ART nodes with the `EventIds` of `Enter` or `Value` events. The generation of the ART is mostly a sequential writing processes: If the ART is stored in a sequential data structure such as a file, then new nodes can be joined at the end; however, a few updates and also reading operations of the existing partial ART are needed.

Figure 13 defines the translation as a Haskell function `mkArt`. During the traversal the translation function `go` keeps track of a stack of `Chains` and the `NodeId = EventId` of the event currently being processed. The function `writeConnect` adds one node to the ART data structure and modifies it in other places; that is, if the newly written node is the beginning of a chain, then the node that it is an argument of is updated (`writeArg`); otherwise it is a later entry in a chain and the reduction pointer of the preceding node is updated (`updateReduction`). Hence a component pointer always points to the first node of a reduction chain.

A variable of type `Chain` stores where the chain currently being traversed belongs into the ART. At the beginning of a chain its value is the data constructor `Context` carrying the `NodeId` of the node of which the chain is a component and the `Branch` to identify exactly which component it is. Later the data constructor `Last` carries the `NodeId` of the last node of the chain that has already been translated. As chains are nested, our translation uses a stack of `Chains` (i.e. a list). Translation of an `Enter` event puts a new `Context` on the stack, translation of a `Value` event removes a chain from the stack.

The translation of `Con`, `Var` and even `App` events is relatively simple. Each gives rise to the construction of a corresponding ART node.

The translation of a `LamVar` event is more complex. Translation uses the function `directionLookup`, which given the node that represents the root of the left-hand side for this  $\lambda$ -bound variable plus the list of branches and the current partial ART, returns the node that is the root of the value of the variable. We have to distinguish two cases:

- If we are at the beginning of a chain, then the  $\lambda$ -variable is a component, not the right-hand side of an equation. We get the parent node of the context node; that is the root of the left-hand side of the equation in the ART. From that node `directionLookup` obtains the beginning of the chain of the  $\lambda$ -bound variable. The argument specified by the `Context` is updated with the node beginning that chain. That node is used for updating the argument specified by the `Context`.

For example, the  $\lambda$ -bound variable `xs` of the equation for `<|>` in Figure 1 has the branch list `[R]`. Hence the right argument of node 26 is the node 38 in Figures 2 and 4.

- If we are in the middle of a chain, then the  $\lambda$ -variable is the right-hand side of an equation. That equation defines a projection. From that last node `directionLookup` obtains the beginning of the chain of the  $\lambda$ -bound variable. That node is the component of the new indirection node that is added to the ART, connected by reduction pointer from the last node.

For example, the right-hand side of the first equation of `mp1us` in Figure 1 is just the  $\lambda$ -bound variable `mr`, which has the branch list `[R]`. Therefore the reduction pointer of node 18 points to an indirection node 60 whose component is node 45 in Figures 2 and 4.

## 6 A PROTOTYPE: HATLIGHT

`HatLight` is our prototype implementation of the new method for creating an ART. `HatLight` is mainly a Haskell library that defines the tracing combinators and the translation from event sequences to an ART. Both event sequence and ART are data structures in memory, not in files. `HatLight` outputs the event sequence and ART, but also writes the ART into a file using the DOT graph description language.<sup>6</sup> Thus the ART can be visualised with a tool such as `GraphViz`.<sup>7</sup> `HatLight` also includes a tracing standard library, which includes some frequently used functions and types. Currently `HatLight` consists of approximately 570 lines of Haskell code.

All the transformed programs, event sequences, ART data and visualisations of the ART in this paper have been obtained with `HatLight`. The definitions of the combinators and the translation are excerpts of `HatLight`.

To gain an insight into the overhead of tracing, we modified our prototype to write the event sequence into a file. The event sequence contains all information needed to construct an ART and it is of similar size. We measured the runtime of the original and traced versions of two programs, each with two different parameters. The program `nfib` determines by simple, exponential recursion the Fibonacci number of the parameter. The program `perms` outputs all permutations of the list of numbers from 1 to the parameter. It uses the definitions given in Section 9.4 of Hutton (2016); all list functions, including `map`, `(++)` and `concat` are traced. The table in Figure 14 gives the measurements obtained on a MacBook Air with flash storage, after compilation with the Glasgow Haskell compiler<sup>8</sup> version 7.8.3 with flag `-O2`.

The slowdown factor of runtime is substantial. The table also shows that the computations produce huge trace files, each of which contains many events. Therefore we wrote a Haskell program that just writes the same number of lines; each line is a constant string of length 9, so that the file size is similar to the corresponding event sequence file. The last column in the table gives the runtimes of this program. Thus we see that more than half of the runtime of a traced program is needed just for writing the event sequence file. So to reduce the slowdown factor in the future, we will have to

<sup>6</sup>[https://en.wikipedia.org/wiki/DOT\\_\(graph\\_description\\_language\)](https://en.wikipedia.org/wiki/DOT_(graph_description_language))

<sup>7</sup><https://www.graphviz.org>

<sup>8</sup><https://www.haskell.org/ghc>

program	original runtime /s	traced runtime /s	slowdown factor	number of events	trace file size /B	writing time /s
nfib 23	0.007	2.92	417	4,497,648	44,976,480	2.30
nfib 25	0.008	8.27	1034	11,775,073	114,970,504	5.90
perms 7	0.015	0.74	49	902,535	8,782,879	0.48
perms 8	0.080	5.96	75	7,731,770	77,873,134	3.83

Figure 14: Tracing measurements for two example programs.

speed up file writing. Our prototype uses the simple but inefficient line

```
hPutStrLn handle (show event)
```

to write an event into the file.

Nonetheless, the runtime overhead and the file sizes clearly demonstrate that we should not trace every reduction of a program. In Section 8 we will discuss how we can trace only part of a program.

### 7 COVERING THE COMPLETE LANGUAGE

Since 2002 Hat works for all of Haskell 98 plus a few common extensions such as multi-parameter classes and functional dependencies. Hence its definition of the ART covers all of Haskell. However, we still have to ensure that our new method for generating an ART works for all of Haskell.

#### 7.1 Types and Classes

Haskell has a complex system of types and classes. Because our transformation changes expressions without changing their types, we do not transform type or class definitions, only the definitions of bodies of methods in class instances. Hence our method is agnostic of the type and class system and its implementation is not affected by any extensions of that system.

#### 7.2 Local Definitions

Consider the following function definition that makes use of a locally defined function. The function `snoc` appends an element to the end of a list.

```
snoc :: a -> [a] -> [a]
snoc x xs = go xs
  where
    go [] = [x]
    go (y:ys) = y : go ys
```

We can transform the right-hand side of each defining equation as before, but we face one problem: The variable `x` is used in the body of the definition of the local function `go`, but it is  $\lambda$ -bound on the left-hand side of the enclosing definition of the top-level function `snoc`. Hat generates an ART for this program, but it was noticed that presenting applications of a local function without the values of its free variables can yield to confusing views. For example, `hat-observe` could produce an output such as

```
go [] = [0]
go [] = [42]
```

However, Hat’s ART contains more information than the ART data structure given in Figure 3. Every variable node has a Boolean flag that indicates whether this is a local variable that may have free variables. Every variable node stores the beginning and end of its

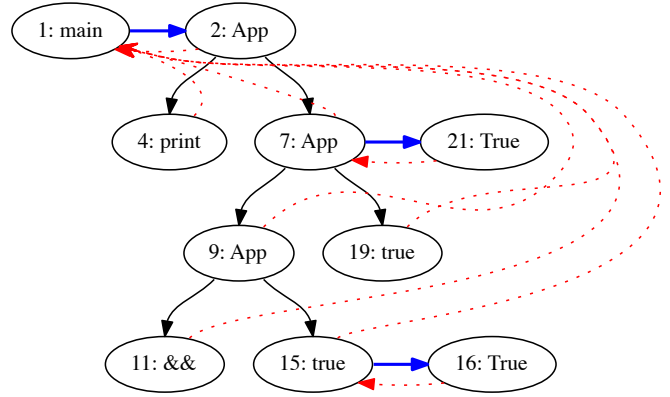

Figure 15: An ART that is incomplete because of a constant.

definition in the source code. Thus it is easy to determine whether one variable is defined locally within the definition of another variable. Although the chain of parents (parent, grandparent, grand-grandparent, etc.) of a node is information about the dynamics of a computation, for a local variable the chain of parents includes the redex roots of all enclosing variables. Thus the ART has the information to determine for any local variable the redex roots of all its enclosing variables. Hence `hat-observe` can produce an output like

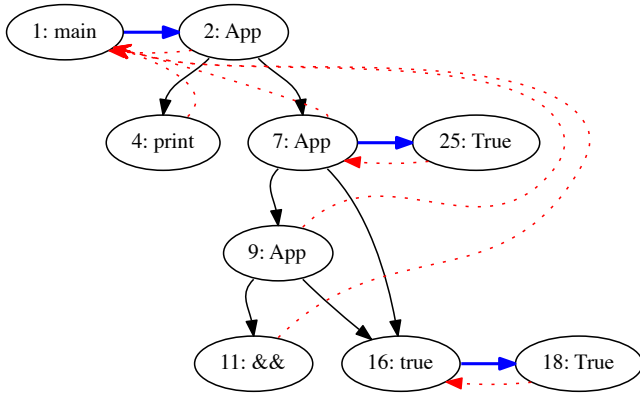

```
(snoc 0 []) .go [] = [0]
(snoc 42 []) .go [] = [42]
```

We can extend `HatLight` to also record for every `let`-bound variable a Boolean flag and information about the beginning and end of its definition in the source. Furthermore, `HatLight` needs to include in the event for a  $\lambda$ -bound variable a counter of how many levels of enclosing redexes to go up before following the list of branches as described in Section 2.3.4;<sup>9</sup> Thus `HatLight` could generate the correct ART also for programs with local definitions as above.

#### 7.3 Constants

Although by definition Haskell is only a non-strict language, all implementations provide a lazy semantics and thus ensure that every constant is computed at most once with its value being shared by all use occurrences. We call a `let`-bound variable in a program a constant, if it appears alone on the left-hand side of its defining equation, that is, it is not a function identifier with parameters on

<sup>9</sup>This counter corresponds to the de Bruijn index of  $\lambda$ -calculus.

**Figure 16: An ART that shares the constant true correctly.**

the left-hand side.<sup>10</sup> In our introductory example `binaryDigit` and `main` are constants and they are the only constants. Because each of these constants is used only once, our tracing method works fine. However, if a constant is used twice or more, then the tracing method fails. Consider

```
true :: Bool
true = True
```

```
main = print (true && true)
```

With our method we obtain the incomplete ART shown in Figure 15

The node `15: true` reduces to the result `16: True`, but there is no reduction edge for node `19: true`. The reason for the problem is simple: the constant `bool` is only evaluated once and the resulting value `True` is stored and not recomputed when the value of `true` is demanded again; however, our tracing works by side-effects that only happen when computation happens. This effect may not only lead to missing information in an ART, but we may obtain an invalid event sequence that cannot be translated into an ART at all. That happens for example for the following program:

```
pair :: (Int,Int)
pair = (6,7)
```

```
fst (x,_) = x
snd (_,x) = x
```

```
main = print (fst pair * snd pair)
```

The first occurrence of `pair` yields a reduction chain in the event sequence, but the second occurrence does not. However, the body of the function `snd` is a  $\lambda$ -bound variable with branch list `[R,R]`. Following this direction in the partially constructed ART fails, because there is no second `pair` constructor in the ART.

Hat handles constants (Chitil et al. 2003). The computation of a constant is shared in its ART. The ART has a special node for the use

<sup>10</sup>There is a difference between the term *constant* and the established term *constant applicative form (CAF)*: A constant bound to a  $\lambda$ -abstraction is not a CAF. In this paper we do not discuss  $\lambda$ -expressions, but Section 8 indicates that we also have to handle constants that are bound to  $\lambda$ -abstractions in the way described here.

occurrence of a constant. That node is similar to an indirection; its component pointer points at the single shared value of the constant. There is no single parent for a constant, because the constant can be used by many redexes of the computation. In early versions of Hat the parent pointer of a constant does not point to any of its parents; in later versions of Hat a constant has a list of parent pointers, one for each parent redex. It is unclear whether the additional time and space overhead for storing this list is worthwhile for the views.

We recently enhanced our new method for generating an ART to handle constants. Because a constant is computed only once, its computation is recorded only once in the event sequence and thus the ART. We added a new event and new combinator for each use of a constant. Thus we can connect several uses of a constant to the single chain for the constant. Figure 16 shows the resulting ART for the first example of this section. In our current version a constant has no parents. This enhancement also works for recursively defined constants, but it is still experimental, because it may not work well in combination with untraced code, which we discuss in Section 8.

## 7.4 Exceptions

A computation of a program may explicitly raise an exception. Any runtime error and also the abortion of a computation by the programmer raises an exception. We can handle these by adding an exception handler in the combinator `eval`. When an exception is raised all reduction chains that are still open can be terminated with an exception value and the event `Value`.

## 7.5 Desugaring

Haskell has many language features that can be desugared into a small subset of the language. For example, a list comprehension can be desugared into the use of a few list combinators. However, for the end user it is desirable that a view of the ART shows an expression as it is in the program. That will require extending the ART data structure and extending every view accordingly.

Desugaring is a temporary solution to obtain a tracing system for Haskell quickly, but in the long term every language construct will need to be supported directly.

## 7.6 Challenges

Haskell's monadic input/output functions and also functions for imperative state such as those using the `ST` monad can be handled by HatLight in principle, by wrapping the untraced primitive functions, as outlined in Section 8. Hat even extends the definition of the ART for some simple output functions to record the characters that they output more directly. However, for tracing any program that makes substantial use of these functions we still have to find a good way of presenting the computation to the user.

By definition Haskell is a sequential language, but its most popular compiler, the Glasgow Haskell compiler, provides it with several different application interfaces for concurrent programming. Our lightweight tracing method generates a sequence of events; the order of these events is essential for reconstructing the ART. Hence our method works only for tracing a sequential computation, at best a single thread of a concurrent computation. The most simple extension to handle many concurrent threads would assume to

have at runtime access to an identifier of the current thread and add this identifier to every event. Thus for every thread an event sequence could be determined and an ART-like trace be reconstructed. In practice, much further research will be needed to find a good way of presenting a concurrent computation to the user, probably specific to the particular concurrency application interface that the program uses.

## 8 UNTRACED CODE

Our new method works well for transforming and then tracing the computation of a complete program. However, in general programmers do not want to trace the computation of all code of a program. When a program uses a library, the programmer usually does not want to see the details of library-function computations. Additionally, tracing creates a time and space overhead that the programmer wants to limit to the parts of the program that they are interested in.

Hat also transforms untraced code, using a slightly different transformation and different combinators. That way untraced code has the same transformed types as traced code and both can easily be combined. Hat’s method is pragmatic but not perfect: the untraced code still writes some superfluous information into the ART file while missing out some essential parts. Because our new method for generating an ART leaves the types of all expressions unchanged, combining transformed and untransformed code is not hindered by changes in types.

It is highly desirable to combine transformed and untransformed code. Untransformed code will always be more efficient and it may use some language features that the program transformation does not (yet) support. Also, transformed code still has to use some untransformed primitive functions, for example for arithmetic and input/output.

Combining traced and untraced code requires some thought. The computation of a function in untraced code is not traced, but that function returns a value to the traced world. Hence that value needs to be recorded in the trace. Both the Hat and the HatLight program transformations can easily handle a call to an untraced first-order function by wrapping it in a combinator that records the result value in the trace when it is returned from the function.

In a higher-order programming language, that value may be a function or a data structure that contains functions. The ART represents a functional value as a function identifier or a partial application of a function identifier. It is unclear how any wrapper could record that function identifier in the ART. Worse, if that function identifier is defined in untraced code, in particular if it is a local function of some black-box library, it should not appear inside the ART. So the definition of the ART does not fit with the concept of black-box untraced code.

We see the solution to the problem in representing a functional value that is returned from untraced code not intensionally, but extensionally, that is, as a finite map from arguments to results. For example for the program

```
main = print (map (+ 1) [1,2,3])
```

the value of `(+ 1)`, and thus also the argument for the function `map`, can be represented as

```
{1 ↦ 2, 2 ↦ 3, 3 ↦ 4}
```

The algorithmic debugger `hoed-pure` uses this representation of functional values and it is also based on first generating a sequence of events which afterwards is translated into its computation tree (see Section 9.3). Hence merging the method of `hoed-pure` into `HatLight` is a feasible future goal.

## 9 RELATED WORK

### 9.1 ART and Hat

The Haskell tracer `Hat`<sup>11</sup> produces an ART for a Haskell program. The design of the structure of an ART started with the redex trail trace developed by Sparud and Runciman (1997a,b). That redex trail only allowed trace exploration as later implemented in `hat-trail` and described in Section 9.1. A comparison of three different tracing systems for Haskell lead to the conclusion that different views of a computation are useful (Chitil et al. 2001). A small addition to the redex trail structure, namely reduction pointers, yields an augmented redex trail (ART) that can support all three views. Wallace et al. (2001) implemented this addition and the three views. Claessen et al. (2003) give the most extended examples of what Hat does from the user’s point of view. Later Chitil (2005) and Silva and Chitil (2006) explored further views and uses of the ART. Chitil et al. (2003) define Hat’s program transformation for generating an ART and later Chitil and Luo (2007) defined the ART structure formally and proved basic properties.

*Multiple Views.* To appreciate the structure of the ART, we briefly review some of the views of an ART that Hat provides.

The viewing tool `hat-observe` is inspired by Hood (see Section 9.3). For a given function identifier it lists all the arguments that the function was applied to during a computation plus its results. For example, for the function identifier `lit` it shows

```
lit _ [] = Nothing
```

removing duplicates, and for the function identifier `mplus` it shows

```
mplus Nothing Nothing = Nothing
```

An observation can be obtained from a single linear traversal of the ART. When `hat-observe` is started, it first creates an index of every identifier occurring in the ART to speed up every later search. Component edges enable reconstruction of expressions and reduction edges point to the result value of a redex.

The viewing tool `hat-trail` allows exploring the history of an expression backwards: it tells that the argument `Nothing` of `print` was created by the reduction of `mplus Nothing Nothing`. The second `Nothing` of that redex was created by the reduction of `lit _ []`. The first application of that redex was created by the reduction of `binaryDigit`. Finally `binaryDigit` was created by the reduction of `main`. In every step the programmer can select any subexpression of a given expression and ask for its parent. Below a selected subexpression is underlined and its parent is given in the subsequent line:

```
print Nothing
<- mplus Nothing Nothing
<- lit _ []
<- binaryDigit
<- main
```

<sup>11</sup>[projects.haskell.org/hat/](http://projects.haskell.org/hat/)

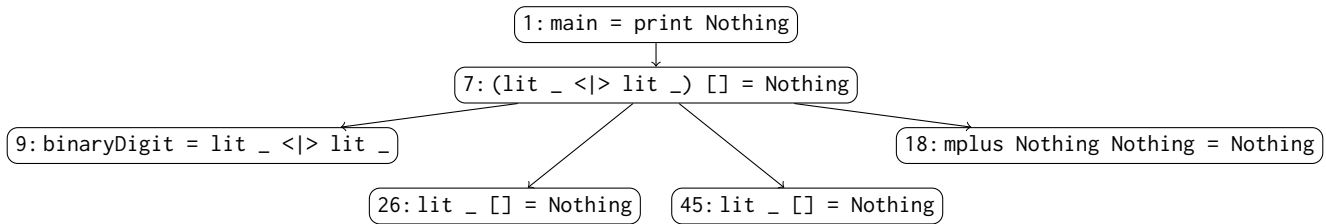

Figure 17: Evaluation dependence tree (EDT) obtained from the ART shown in Figure 2.

Thus `hat-trail` enables exploring a computation backwards; debugging goes from a noticed failure backwards to the program defect that caused it. Parent edges are essential for `hat-trail`'s functionality; `hat-trail` reconstructs expressions from component edges.

The viewing tool `hat-detect` is an algorithmic debugger for semi-automatically locating a defect in a program. At the heart of algorithmic debugging is a computation tree, a structured representation of a computation. Figure 17 shows the computation tree, an evaluation dependence tree, constructed by `hat-detect` for our example. Every node is a computation statement: a redex plus its result value (we consider `print Nothing` as a value of type `IO ()`). Here we include the ART node identifier of the redex in each tree node to emphasise the relationship. The tree gives insight into the computation, but because our program shows no failure, we cannot do any debugging. The tool `hat-detect` constructs the evaluation dependence tree on the fly from the ART, using all three sorts of edges.

Most debuggers used in practice, especially for imperative programs, are stepping debuggers. A stepping debugger is a very special instance of an algorithmic debugger; the stepping debugger only allows a linear, forward traversal of the computation tree. This relation between stepping debugger and computation tree is central to the work of Braßel et al. (2007), which we discuss later. The ART could be used as basis for a stepping debugger similar to the one of Braßel et al. (2007).

Many other uses of an ART have been discussed and/or implemented, for example, a virtual stack trace and dynamic program slicing.

*A Structural Differences.* The ART structure as shown in Figure 2 and generated by our new method differs from Hat's ART in one point: A component pointer is `noId`, when the component was never demanded during the computation. In contrast, Hat's ART always has a valid component pointer to the root of an (unevaluated) expression. Recording such an unevaluated expression would be possible in principle, but substantially complicate our method. The additional information about unevaluated expressions seems of little use. To prevent information overload, displayed expressions should avoid any unnecessary information, and Hat's viewing tools already offer showing such unevaluated expressions just as `_`.

## 9.2 Other Algorithmic Debuggers for Lazy Functional Languages

Besides `hat-detect`, several algorithmic debuggers (Shapiro 1983) for Haskell have been developed. Nilsson and Sparud (1997) define the evaluation dependence tree (EDT) as a suitable computation tree for algorithmic debugging of lazy functional programs. Nilsson's algorithmic debugger `Freja` generates an EDT (Nilsson 1998, 2001). `Freja` does not generate a more general trace like the ART. `Freja` is a complete compiler for a subset of Haskell and compiler and runtime system together enable the generation of the EDT. Therefore debugging with `Freja` has only modest runtime overheads, but a complex tracing architecture integrated with a compiler makes supporting a large and evolving programming language such as Haskell very hard. In contrast our lightweight method permits us better to explore the design space of tracing and will hopefully enable us to build the first omniscient debugger that will be used for real-world Haskell programs. `Freja` already handles many language features discussed in Section 7. In particular, `Freja` records the names of all variables, including  $\lambda$ -bound variables, and for each locally defined variable it records the set of its free variables together with their values. Thus `Freja` can provide inspiration for an alternative, possibly more friendly user interface to some language features. `Freja` requires all higher-order functions to be traced, even though the workings of trusted higher-order functions is not recorded; in contrast we outlined in Section 8 how we plan to use untraced higher-order functions.

Pope (2005, 2006) built the algorithmic debugger `Buddha` for Haskell. Generation of the computation tree is based on program transformation, which, however, is still integrated with an existing compiler, the Glasgow Haskell compiler. `Buddha` can represent functional values as finite maps and Pope stated that a computation tree with functional values as finite maps has to have a structure that is different from the EDT. Subsequently Chitil and Davie (2008) defined the new computation tree structure formally by relating it to the ART, named it the function dependence tree (FDT), and proved its soundness for algorithmic debugging.

## 9.3 Hood and Hoed

Our new method for obtaining an ART was inspired by Andy Gill's work on observing the values of expressions in lazy functional programs, which he implemented in his Haskell debugging library `Hood` (Gill 2001). A programmer using `Hood` annotates their program with the `observe` combinator. At runtime these annotations

generate a sequence of events. Finally, when computation terminates, the Hood library reconstructs observed values from the sequence of events. These values can be values of data types, that is, applications of data constructors and primitive values such as 42 and 'a', or functional values. A functional value is represented extensionally, that is, as a finite map from arguments to results, as we discussed in Section 8. To sum up, Hood does not generate any trace structure from its sequence of events, but a set of values.

We identified and generalised Hood's use of "identity" functions with side-effects and its use of event references to record expression nesting. Hood's `Enter` events inspired our novel method of delimiting chains of reductions in the event sequence. Hood does not record such chains; it does not need them for observing only values.

Faddegon and Chitil (2015) combined Hood's instrumentation with the cost centre stacks of the profiling system of the Glasgow Haskell compiler to obtain a computation tree for algorithmic debugging of Haskell programs. The implementation `hoed-stack` uses Hood's event sequence to obtain computation statements as nodes of the computation tree and the cost centre stacks are used to connect these nodes to a tree. The computation tree is a function dependence tree, not an evaluation dependence tree (cf. Section 9.2).

Subsequently Faddegon and Chitil (2016) discovered that cost centre stacks are not needed, but that the very same sequence of events that Hood generates already contains sufficient information to connect the nodes of computation statements to a tree. The central insight is that events come in pairs, an `Enter` event is later followed by an event describing the weak-head normal form of a value. From the nesting structure of these event pairs the structure of the computation tree can be obtained. Because of higher-order functions, the relationship between nesting of event pairs and the computation tree structure is quite complex. The implementation of this algorithmic debugger is called `hoed-pure`.

Here, in this paper, we follow Hood in instrumenting a program with combinators that generate a sequence of events. However, Hood traces only values and except for function identifiers so does Hoed. To obtain the richer information needed for an ART, we use a richer set of events. For example, we have events for both `let` and `λ`-bound variables. Instead of the event pairs of Hood we have chains of events, starting with an `Enter` and ending with a `Value` event, but with an unbound number of events in between. Hood's and Hoed's program annotations are far more lightweight than the instrumentation introduced by our program transformation. Hoed requires only one annotation in the definition of each function of interest. Its `observe` combinator recursively traverses a data structure while recording it in the sequence of events. In contrast, we annotate every subexpression with a combinator. Thus we record a value when it is constructed by the program (the data constructor is instrumented), whereas Hood and Hoed record a value when that value passes through the `observe` combinator which otherwise behaves like the identity function.

Hood and Hoed have the great advantage that they require annotating only functions of interest; most of a program may be left unchanged. The connection of computation tree nodes based on nested event pairs works even when an arbitrary number of untraced function calls are performed in between. In contrast, our

method for constructing an ART is based on transforming the complete program. This whole-program tracing is the premise for being able to transform the event sequence into the ART, a single connected graph. As we discussed in Section 8, extending our method to work with untransformed modules will probably require combining it with the method of `hoed-pure`.

Finally our method for constructing an ART has the advantage that it preserves sharing of expressions in the heap of the instrumented program, whereas the `observe` combinator loses sharing. Hence for Hood and Hoed the execution of an annotated program can require more space and the event sequence contains much duplication, compared to the ART.

## 9.4 Other Debuggers for Lazy Functional Languages

Perera et al. (2012) define another tracing model for lazy functional programs that is based on program slicing. They prove several desirable properties for their approach. It would be interesting to establish whether the ART meets similar properties, which the work of Silva and Chitil (2006) suggests.

Marlow et al. (2007) describe a different approach to debugging Haskell programs. They describe how a traditional stepping debugger can work and be implemented for a lazy functional language.

Braßel et al. (2007) present a debugging approach for Haskell that views a computation in a combination of a traditionally stepping debugger and an algorithmic debugger. For eager evaluation these two views are closely related. The central idea is that a small trace states which reduction steps an eager evaluator should skip to perform exactly the same computations as a lazy evaluator. This trace is generated by an initial lazy computation of the program. The viewing tool then uses an eager evaluator of Haskell together with the small trace to provide a view of eager evaluation that "magically" skips unnecessary steps. This approach fits well with our observation that the ART structure is independent of the order of evaluation. The main obstacle in practice is that for a lazy language there is hardly ever an eager evaluator available but it must be implemented from scratch.

## 10 CONCLUSIONS

We have presented a new method for generating a detailed trace of a lazy functional computation. We have shown that the simple idea of instrumenting a high-level program such that it generates events at well-defined points of the computation can yield detailed information about how a computation works; this technique, first introduced by Gill (2001), clearly has many potential application areas. We have described and justified every step of the new method. Our implementation `HatLight` establishes that the method works.

The fact that our tracing combinators do not change types may be seen as a disadvantage: A mistake in Hat's program transformation is likely to yield programs that do not compile but raise type errors. Thus such a mistake is soon noticed. However, in our experience also mistakes in the new program transformation are likely to yield programs that raise type errors.

We could complete `HatLight` to write the ART into a file in the same format as used by Hat, such that all of Hat's viewing tools could be used. However, our aim in the near future is to use `HatLight`

as an experimental platform for modifications and extensions as discussed in Sections 7 and 8. For that purpose HatLight needs to stay small and allow for useful variations of the ART that are incompatible with Hat. The difference discussed in Section 9.1 is already such a variation.

With different combinators our method should also work for strict functional programming languages. However, because these languages are generally not pure, recording of side-effects in the ART will be important. Hat currently supports basic input-output effects in its tracing and ART, but further work in this area will be required.

## ACKNOWLEDGMENTS

We thank the reviewers, in particular Henrik Nilsson, for their valuable comments and helpful suggestions.
