Abstract

The defect density of a material is decisive for its physical, chemical and mechanical properties. Accordingly, defect tuning is desirable for applications spanning, e.g., batteries, fuel cells, electronics, optics, catalysis and mechanical strength and resilience. Here we simulate the mechanochemical synthesis of the perovskite Ba$_{1-x}$Sr$_x$LiF$_3$ by compressing a BaLiF$_3$ nanoparticle with a SrLiF$_3$ nanoparticle under conditions likely to occur during high-energy ball milling. We investigate the crystallization process and the ionic mobility of the system and compare with experiment. Animations of the crystallization, simulated under high pressure, revealed that cations, within the crystallization front, would commonly condense onto ‘incorrect’ lattice sites, in some cases eventually leading to the formation of anti-site defects. However, most of these cations would then re-amorphise and the ‘correct’ cation would take its place — rectifying the defect. Crucially, it is the amorphous/crystalline interface that enables such repair because the ions are mobile in this region. The simulations reveal high ion mobility close to the anti-site defects and other defective regions, but no ion mobility in the defect free regions of BaLiF$_3$. The MD simulations indicate that high-energy ball milling might reduce the anti-site defect density in a material by exposing these defects to the surface or creating amorphous regions within the crystallite which then would allow localized recrystallization, enabling defect repair. This assumption is a possible explanation for the reduced ion mobility, revealed by NMR spectroscopy, and, thus, most likely smaller defect density in BaLiF$_3$ prepared by high-energy ball milling compared to thermally synthesized BaLiF$_3$ samples.

Introduction

The properties of a functional material are governed by its defect density; the latter derives, apart from temperature and size of the system, from the synthetic pathway used in its fabrication. Typically, high defect densities, and associated high ionic mobility, are desirable in ceramics with applications for fuel cells or batteries$^{[1,2]}$, albeit defects can sometimes reduce the ionic conductivity$^{[3,4]}$. Conversely, materials with low defect densities are inter alia needed for LEDs$^{[5,6]}$, photovoltaics$^{[7]}$ and optical devices$^{[8,9]}$. Moreover, defect tuning is widely used to modulate the catalytic activity of a material$^{[10,11]}$. Defect tuning is therefore pivotal to the exploitation of a functional material possessing a diverse range of properties and hence applications. Defect control, via ‘work hardening’ — analogous to ball milling — strengthens a material via plastic deformation and recrystallization below its melting temperature and has been exploited for millennia. However, the implications of defect modulation of nanomaterials are less well developed. Such knowledge will be critical for the mechanical resilience and preservation of properties of the functional material during its operational lifespan. $^{[12]}$. 
An important class of materials, with applications including catalysts, ion conductor, dielectric, piezoelectric, photovoltaic, are the perovskites, ABX₃. In this class, BaLiF₃ is a rare example of a cation inverted perovskite. It is a potential material for vacuum-ultraviolet lasers and lenses because of its large band-gap. The material is also an interesting model system to study ion conduction, since it contains two light ions, F⁻ and Li⁺, which are likely to be mobile in the system. Although this issue was addressed in theoretical studies, there is a lack of experimental data. Previously, we reported a higher ionic conductivity of nanocrystalline BaLiF₃ prepared by ball milling equimolar mixtures of BaF₂ and LiF, compared to thermally prepared micro or single crystalline BaLiF₃. Interestingly the higher ionic conductivity comes along with a smaller ionic mobility of the majority of the ions, as revealed by temperature variable ⁷Li NMR measurements. Mechanosynthesis generally offers a fast, easy and inexpensive method of fabricating nanocrystalline materials including metastable ceramics which are difficult to prepare using alternative methods. Hence, it was possible to substitute up to 40 % of the Ba ions in BaLiF₃ by Sr ions using a mechanochemical approach, forming metastable Ba₁₋ₓSrₓLiF₃, which exhibits a very similar ionic conductivity as mechanochemically prepared BaLiF₃. The reaction mechanism was investigated by ¹⁹F magic angle spinning (MAS) NMR spectroscopy. It was found that the replacement of Ba ions by Sr ions starts after the formation of BaLiF₃. In this study, we use Molecular Dynamics (MD) to simulate a part of the ball milling process, i.e. the impact of a milling ball compressing a BaLiF₃ nanoparticle with a SrLiF₃ nanoparticle leading to the formation of Ba₁₋ₓSrₓLiF₃. Specifically, we simulate the crushing and subsequent amorphisation of BaLiF₃/SrLiF₃ nanoparticles under high temperature and pressure, the amorphous-to-crystalline phase change, and finally, the F and Li ionic mobility within the ‘ball milled’ model system. We couple our simulations with ¹⁹F and ⁷Li NMR measurements on the real materials, synthesized using high-energy ball milling and thermal annealing, to determine the ionic mobility.

**Methods**

**Computational**

**Generating Atomistic Models**

A spherical nanoparticle of BaLiF₃ with cation inverted perovskite structure was generated, using crystallographic data taken from ref [35]. In one half of the nanoparticle, the Ba ions were replaced by Sr; the number of atoms in the simulation cell was: Ba = 4133, Sr = 4127, Li = 8186, F = 24706. We note that the stoichiometry was not set exactly to ABX₃, this was to ensure that the stoichiometry did not bias artificially the evolution of a perovskite structure. The nanoparticle was then ‘crushed’, using MD simulation, performed at high pressure and temperature, to mirror an impact of a milling ball onto the particle, fig 1. Specifically, MD simulation was performed at 5 GPa and 1000 K for 107 ns under an NPT ensemble (constant Number of ions, constant Pressure and constant Temperature). The simulation thus facilitates a BaLiF₃ nanoparticle crushed together with a SrLiF₃ nanoparticle. Under these simulations conditions of crushing a BaLiF₃ nanoparticle with a SrLiF₃ nanoparticle, the SrLiF₃ nanoparticle first amorphised and then crystallized, which required about 107 ns. After crystallisation, ionic mobility data of F and Li ions in the model system was collected (at 0 Pa and 600 K).

This (single) simulation required 250,000 cpu hours; the high computational cost was attributed to crystallization ‘errors’ and repair mechanisms. Viewing the crystallization animations revealed that several defects evolved in each atomic layer – most of which were repaired. We presume that this ‘defect evolution and repair’ process resulted in the high computation cost. We surmise that the crystallization front only moved forward once most of the defects were repaired enabling a lower configurational energy. It is likely that the Madelung field is integral to crystallization and that any perturbation of this field reduces the propensity for other ions to
spontaneously order at the crystallization front. Previous simulations, performed on binary oxides, such as CeO₂ and TiO₂,[36,37] typically required an order of magnitude less computational time.

**Potential Model**

The Born model of the ionic solid was used to describe the Ba₁₋₅SrₓLiF₃ in which the component ions interact via short-range parameterized interactions coupled with long-range Coulombic interactions, equation (1).

\[
E(r_{ij}) = \sum_{ij} \frac{Q_i Q_j e^2}{4 \pi \epsilon_0 r_{ij}} + \sum_{ij} A \exp\left(-\frac{r_{ij}}{\sigma}\right) C r_{ij}^6
\]

(1)

The potential parameters, table 1 (SI), were taken from ref. [24] using a rigid ion model. The Sr-F interaction was derived by potential fitting to the SrF₂ structure and elastic[38] and dielectric[39] properties using the GULP code[40]. All the MD simulations were performed using the DL_POLY code[41].

We note that the potential model was capable of generating a perovskite-structured Ba₁₋₅SrₓLiF₃ nanomaterial together with defects typically found in the real material such as anti-site defects and stacking faults. Moreover, such crystal and micro structures evolved from an amorphous precursor, where interatomic distances were far from equilibrium values. This proffers confidence in that the potential model is both robust and accurate.

**Experimental**

**Synthesis**

Ba₁₋₅SrₓLiF₃ was prepared by milling mixtures of LiF (99.99%, Alfa Aesar), BaF₂ (99.99%, Sigma Aldrich) and SrF₂ (99.99%, Alfa Aesar) in a planetary ball mill (Pulverisette 7 premium line, Fritsch, Germany) with an overall mass of 2.000(1) g employing a milling beaker (45 mL) filled with 140 milling balls with a diameter of 5 mm made of stabilized ZrO₂ (Fritsch, Germany). The total milling times were altered for the different compositions. If not stated otherwise, for the pure BaLiF₃, an equimolar mixture of BaF₂ and LiF was milled for 6 h. The Ba₁₋₅SrₓLiF₃ samples were milled for 20 h. The microcrystalline BaLiF₃ is identical to the one reported in refs. [26,27] prepared by annealing mechanosynthesised BaLiF₃, which was since then stored under vacuum in a glass ampoule and stayed phase pure this way.

The BaLiF₃ single crystal is identical to the one reported in ref. [26] and was prepared by the procedure described there: At first, the starting materials, BaF₂ (crystal pieces) and LiF (GFI, ‘optical grade’) were purified by a pre-treatment, i.e. the materials were treated with hydrofluoric acid at elevated temperatures. Subsequently, they were mixed in the required ratio and subjected to a zone melting procedure under HF. Since BaLiF₃ melts incongruently at about 1100 K, the composition of the starting materials has to deviate from the composition of the crystal. The chosen composition was Ba₀.₈₆Li₁.₁₄F₂.₈₆. The crystal was grown in a platinum crucible by conventional Czochralski technique with radio frequency (RF)-heating and automatic diameter control. In order to suppress oxidation of the melt, the crystal was grown in an atmosphere consisting of Ar and CF₄. The growth rate was 2 mm/h and the rotation varied from 10 to 25 min⁻¹. The obtained colorless crystal was 70 mm in length and 18 mm in diameter. XRPD confirmed phase purity[26].

**Measurements**

The ⁷Li and ¹⁹F NMR measurements were conducted with two different NMR spectrometers. The high temperature decoupling experiments were done with a laser heated MAS probe (Bruker Biospin) at an Avance III spectrometer (Bruker Biospin) operating at ν₀(¹⁹F) = 564.7 MHz and ν₀(⁷Li) = 233.3 MHz. The spinning rate of the rotor was set to 3 kHz. Freshly evaporated nitrogen gas was used as bearing gas. For the ¹⁹F NMR measurements a π/2 pulse with duration of 2.5 μs, for the ⁷Li NMR measurements a π/2 pulse with duration of 3.5 μs was used. Four scans were accumulated for each spectrum with a waiting time of 6 x the spin lattice relaxation time, T₁, between the scans to record fully relaxed spectra. The decoupling experiments were done with a robust decoupling program with frequency sweep[42].
The static $^{19}$F and $^7$Li NMR experiments were done with an MSL 400 spectrometer (Bruker Biospin) connected to an Oxford cryomagnet with a nominal field of 9.4 T corresponding to $\nu_0(^{19}$F) = 376.5 MHz and $\nu_0(^7$Li) = 155.4 MHz. The $^{19}$F NMR measurements were performed with a modified 7 mm MAS probe (Bruker), the $^7$Li NMR measurements with a commercial high-temperature probe (Bruker Biospin). For all measurements the saturation recovery sequence was used, followed by an adjustable waiting time (set to $6 \times T_1$ to record fully relaxed spectra) and a single $\pi/2$ pulse with duration of 3.4 μs ($^{19}$F) and 1.8 μs ($^7$Li), respectively. Measurements were done at samples sealed in glass ampoules. The samples were dried in vacuum at ca. 380 K for at least 24 h prior to sealing.

Results

Simulation

Crystallization Simulated ‘ball milling’ of the BaLiF$_3$/SrLiF$_3$ nanosystem results in the amorphisation of the SrLiF$_3$, which thus can be understood as a reaction of the BaLiF$_3$ nanoparticle with an amorphous mixture of SrF$_2$ and LiF similar to experimental observations$^{[30]}$, and leaching of Ba ions into the amorphous material, fig 1(a,b). The (Sr-rich) Ba$_{1-x}$Sr$_x$LiF$_3$ then starts to crystallize – templated by BaLiF$_3$, which acts as a nucleating seed, figs. 1 (c, d).

During crystallization, Li and Ba/Sr ions, in the amorphous region, condense onto the crystalline region and compete for the two (perovskite) cation sites. Animations of the simulated crystallization (cf. SI) reveal that cations often condense onto ‘incorrect’ lattice sites – such as Li on A sites and Ba/Sr on B sites leading to anti-site defects. However, most of these cations re-amorphise and are then replaced by the ‘correct’ cation – fed from the amorphous region -, repairing the anti-site defect, see fig. 2.
Fig. 2: Repair of substitutional defects. (a) Model nanoparticle crushed under simulated ball milling resulting in amorphisation of the SrLiF$_3$. (b) (c) Section cut through the model system during crystallization showing a Li ion, colored yellow, that has crystallized (erroneously) onto the A-site of the perovskite structure. (d) as (c) but after further MD simulation, which results in the Li moving off the A-site (dissolution) and is subsequently replaced by an Sr ion repairing the defect. Li is colored yellow, Sr is white and Ba is red (F ions are not shown).

Crucially, an exchange of cations can only take place if the defect is in direct contact with the amorphous phase because it enables ion mobility. Conversely, if the crystallization front moves forward before the incorrect ions are replaced, the cations become trapped, resulting in the formation of anti-site defects, figs. 3, S1 and S2.

Fig. 3: A part of the crystallized system characterized by anti-site defects and Ba/Sr intermixing causing lattice distortion.

In our simulations we found the Li ions residing at A sites off center, resulting in a coordination number of 4 or 5 (seemingly depending on the number of Li ions on the site) instead of 12, see fig. S2.

It should be mentioned that the formation of Ba-Li anti-site defects has previously been postulated by several authors.$^{[25,44-45]}$ We therefore provide evidence that their postulate was correct and, moreover, predict a repair mechanism.

It should be noted that SrLiF$_3$, in agreement with DFT calculations$^{[46]}$ predicting SrLiF$_3$ to be unstable, has not yet been prepared experimentally. Following the simulation results, a synthesis at elevated pressure should be tried, because reducing the pressure towards zero in the simulation leads to a phase transformation of SrLiF$_3$ to SrF$_2$ and LiF, which will be discussed in detail in an upcoming paper.

Ionic mobility Analysis, using molecular graphical techniques (see supporting information for more information), reveals high F and Li ion mobility in defective regions of the Ba$_{1-x}$Sr$_x$LiF$_3$ system. These include anti-site defects, Sr/Ba intermixing and edge dislocations/stacking faults, fig 4 and S1 figs S1-S2 and S6. It should be mentioned, that Zahn et al.$^{[25]}$ created Ba-Li anti-site defects intentionally in their simulations to get smaller activation energies for

It should be mentioned that Zahn et al.$^{[25]}$ created Ba-Li anti-site defects intentionally in their simulations to get smaller activation energies for...
Frenkel defect formation which are closer to experimental results.

Fig. 4: F and Li ion mobility in defective regions of Ba$_{1-x}$Sr$_x$LiF$_3$ (a) segment of the model structure showing (top) substitutional defects: Li located on perovskite A-sites and Ba located on B-sites; (bottom) intermixing of Ba and Sr ions on A-sites. (b) superimposed snapshots in time of the MD simulation showing the mobility of the F ions around the defects. We note that domains of perfect BaLiF$_3$ show no F or Li ion transport.

The increased ion mobility in the areas showing Sr/Ba intermixing, which can be ascribed to geometric frustration[47], is in agreement with experiment (fig. 5), reinforcing the validity of the simulations. Conversely, domains of pristine (defect-free) BaLiF$_3$ showed no ionic mobility within the timescale of the MD simulation, figs 4 and 5.

Experiment

In fig. 5, in the two left columns, static $^{19}$F NMR spectra of nanocrystalline (mechanosynthesized) and microcrystalline (annealed) BaLiF$_3$ recorded at different temperatures are shown. The static $^{19}$F NMR spectrum consists of three NMR lines, which was also observed for RbCaF$_3$[48] and RbPbF$_3$[49] and is probably caused by chemical shift anisotropy (the $^{19}$F MAS NMR spectrum, recorded with $v_{rot} = 60$ kHz, displays a single NMR line at 66 ppm for all BaLiF$_3$ samples prepared[26]). The spectra exhibit only subtle changes with temperature. The ones of the mechanosynthesized sample show a growing bulge of the main NMR line, while the NMR spectra of the microcrystalline sample reveal an incipient coalescence of the most intense and the NMR line located at around 45 kHz, both indicating the beginning of fast motion of ions (see figs. S7a-d for $^{19}$F and $^7$Li NMR spectra of the two BaLiF$_3$ samples at higher temperature). On the right side of fig. 5, the static $^{19}$F and $^7$Li NMR spectra of Ba$_{0.74}$Sr$_{0.26}$LiF$_3$ are shown (see fig. S8 for the respective $^7$Li NMR spectra of BaLiF$_3$). The $^{19}$F NMR spectra show the emergence of a narrow NMR line at temperatures above 373 K indicating fast ion motion of the fluoride ions. Also the $^7$Li NMR spectra show a pronounced motional narrowing which was not observed for the mechanosynthesized, pure BaLiF$_3$, see fig. S8. Hence, the replacement of a part of the Ba ions by Sr ions increases the ionic mobility, in agreement with simulation.

Fig. 5: Left two columns: comparison of $^{19}$F NMR spectra recorded at the temperatures indicated of mechanosynthesised (3 h 600 rpm, ZrO$_2$ milling vial set) and annealed BaLiF$_3$ (24 h 870 K). Right two columns: $^{19}$F and $^7$Li NMR spectra of mechanosynthesised Ba$_{0.74}$Sr$_{0.26}$LiF$_3$ recorded at the temperatures indicated. ($v_0^{[19F]} = 376.5$ MHz, $v_0^{[7Li]} = 155.4$ MHz). For comparison the $^7$Li NMR spectra recorded at 630 K and 290 K (red dashed line) as well as the $^{19}$F NMR spectra recorded at 473 K and 373 K are superimposed.

Since the motional narrowing of the $^7$Li NMR spectra can be caused by both, the fast motion of the Li ions as well as the fast motion of the F ions coordinating...
the Li ions due to nuclear dipole coupling, a decoupling of \(^{7}\text{Li}\) and \(^{19}\text{F}\) was done which suppresses the interaction between these two nuclei. This way a motional narrowing of the \(^{7}\text{Li}\) NMR line can only be caused by a motional averaging of the Li-Li (and Li-Ba) interactions, and a motional narrowing of the \(^{19}\text{F}\) NMR line is solely caused by a motional averaging the F-F (and F-Ba) interactions. However, it should be noted, that the F-F interaction is much stronger than the F-Li interaction, such that a pronounced motional narrowing of a \(^{19}\text{F}\) NMR line would clearly be caused by F motion. In fig. 6 the \(^{7}\text{Li}\) and \(^{19}\text{F}\) NMR spectra, with the respective other nucleus decoupled, are shown for the microcrystalline and nanocrystalline BaLiF\(_3\), prepared by high-energy ball milling. In agreement with ref. [27] the microcrystalline sample shows a pronounced motional narrowing of the \(^{7}\text{Li}\) NMR line while the mechanosynthesized sample is characterized by only a slight motional narrowing. The \(^{19}\text{F}\) NMR spectrum of the microcrystalline sample shows the emergence of a narrow line resulting from the coalescence of the NMR lines located around 30 kHz and 100 kHz, starting at ca. 610 K (see figs. S7a-d for other temperatures), while the nanocrystalline BaLiF\(_3\) only shows the beginning of such a process at 740 K.

As displayed in fig. 6, both, the \(^{7}\text{Li}\) NMR spectra and the \(^{19}\text{F}\) NMR spectra show motional narrowing and coalescence, respectively, indicating that both ion species are mobile in both BaLiF\(_3\) samples, which is in agreement with simulation. In case of the microcrystalline sample almost all Li ions appear to be mobile above 700 K, while only a fraction of the F ions are highly mobile. This seems to be in disagreement with the simulations. However, it should be noted, that for Li, much smaller jump rates (ca. 4 kHz) are sufficient for motional narrowing because of the narrow rigid lattice line widths. Conversely, F ion jump rates need to be about ten times larger than Li ion jump rates to cause motional narrowing. Computationally, the ion mobility was captured over a time span of 1 ns at 1000 K (because of computational cost). This translates to jump rates larger than 1 GHz. Accordingly, slow jumps of the Li ions would not be visible in the window of time accessible to the MD simulation. Albeit we do observe some fast Li jumps close to defects.

![Fig 6: Left two columns: On the left \(^{7}\text{Li}\) MAS NMR spectra with \(^{19}\text{F}\) decoupled, on the right \(^{19}\text{F}\) MAS NMR spectra with \(^{7}\text{Li}\) decoupled for microcrystalline BaLiF\(_3\) (\(\nu_{\text{FSF}} = 565\text{ MHz} , \quad \nu_{\text{FSF}}(\text{Li}) = 233\text{ MHz}\)). Right two columns: the same kind of spectra is shown for mechanosynthesized BaLiF\(_3\). The spinning rate was set to 3 kHz. Asterisks denote spinning sidebands. In case of the \(^{7}\text{Li}\) NMR spectra the narrow NMR line at the highest temperature measured is compared with the non-narrowed line of the rigid lattice (dashed red line).](image)

Discussion

The simulation of compressing a BaLiF\(_3\) with a SrLiF\(_3\) particle resulted in the formation of Ba\(_{1-x}\)Sr\(_x\)LiF\(_3\) in agreement with experiment. The formation of very Sr-rich Ba\(_{1-x}\)Sr\(_x\)LiF\(_3\) or even pure SrLiF\(_3\), however, was not observed experimentally which indicates that these species might only be stable at high pressure. After the impact event, which might in fact lead to the formation of SrLiF\(_3\), this compound would decompose again and later on react with residual BaLiF\(_3\) until the reaction, forming Ba\(_{1-x}\)Sr\(_x\)LiF\(_3\), is completed.

The simulation of the crystallization revealed the erroneous crystallization of Li ions at Ba/Sr sites and Ba/Sr at Li sites to be common. Although most of these defects are repaired since they seemingly impede further crystallization (see 'Methods' section), a few wrongly placed cations remained in the crystallized system, creating Ba/Sr-Li anti-site defects. Interestingly, these defects cannot be eliminated within the crystal, which means that their number should be independent of the temperature of the crystallized system, but depend on the synthesis parameters. Hence, the anti-site defect density of
BaLiF₃ might differ for different synthesis temperatures, pressures etc.
The simulations revealed no ion motion in perfectly crystalline BaLiF₃, but only in defective BaLiF₃, notably close to Ba-Li anti-site defects as already proposed by Zahn et al.\textsuperscript{[25]}. Furthermore, the replacement of a part of the Ba ions by Sr ions increased the ion mobility considerably, as shown by simulation and experiment, which is most likely caused by geometric frustration lowering the activation energies for ion migration.

Interestingly, the highest ion mobility was experimentally observed for the microcrystalline and single crystalline BaLiF₃ (figs. 6 and S8) which, however, showed a smaller ionic conductivity than the BaLiF₃ prepared by high-energy ball milling\textsuperscript{[26]} (fig. S10). Also the ionic conductivity of the Ba₁₋ₓSrₓLiF₃ is not considerable increased compared to the one of the mechasynthesized BaLiF₃\textsuperscript{[30]} (fig. S10), despite its higher ionic mobility. Hence, it seems plausible to assume that the ion conductivity of nanocrystalline, mechasynthesized BaLiF₃ and Ba₁₋ₓSrₓLiF₃ is governed by fast ion motion in the grain boundaries as was already assumed\textsuperscript{[26,27]} and is in agreement with simulation (fig. S5).

However, the origin of the different ion mobilities in the different BaLiF₃ samples remains unclear. It should be noted that all BaLiF₃ samples investigated are phase pure and exhibit very similar lattice parameters\textsuperscript{[26,27]}. The simulations indicate a higher defect density in the micro- and single crystalline material than in the mechasynthesized BaLiF₃ since only the defective regions show ion mobility. This might be caused by a contamination introduced during the heat treatment. In fact, the BaLiF₃ single crystal shows an extrinsic part of ion conductivity indicating a contamination of the crystal\textsuperscript{[26]} (fig. S10), despite the very careful synthesis procedure. The annealed microcrystalline sample, however, does not show any extrinsic conductivity in the temperature range measured\textsuperscript{[26]}, see fig. S10. Interestingly, the annealed BaLiF₃ shows a motional narrowing at lower temperature than the single crystal (fig. S8). Since the ionic conductivity of the single crystal is higher in this temperature regime, this indicates a larger number of mobile ions in single crystalline BaLiF₃ than in the annealed sample, supporting the assumption of some sort of contamination of the single crystal.

Another possible explanation could be a reduced anti-site defect density in mechasynthesized BaLiF₃, since this kind of defect fosters ion mobility. In this regard it should be noted that vacancies seem to have no pronounced impact on ion mobility, indicating high activation energies for ion migration and, thus, also point defect formation. While a reduction of the number of mobile vacancies formed during crystallization would not be surprising in a nanocrystal, since they should soon end up at the surface of the crystallite, eliminating the vacancy, such mechanism would not work in case of anti-site defects. We therefore explore whether our simulations can disclose how ball milling could reduce the anti-site defect density.

Our simulations reveal defect repair mechanisms: ions condensing onto ‘incorrect’ lattice sites can subsequently move off the site to be replaced by the correct ion. However, this can only occur at a crystalline/amorphous interface and not deep within the crystal; the ball milling process could therefore facilitate the exposure of anti-site defects, deep within the crystal, to the surface. We now hypothesize as to how ball milling might facilitate this.

During milling, crystallites are repeatedly impacted and welded by the milling balls. We postulate that the repeated high-energy impacts, associated with ball milling, provides sufficient stress to initiate lattice slip - exposing defects, from ‘deep’ within the crystal, to a surface. Moreover, the impacts and the mechanical stress, induced by milling balls rolling over the crystallites, are also likely to cause localized abrasion and amorphisation of the crystallite surfaces\textsuperscript{[50]} and regions near the surface allowing a localized recrystallization. Repair is now possible because anti-site defects can move off their (incorrect) lattice sites and be replaced by the correct ion from within the amorphous region. We also propose that lattice slip along grain boundaries (GB), induced by the mechanical stress associated with ball milling, might enable repair of the GB’s\textsuperscript{[49]}. In particular, previously
we predicted that uniaxial stress acting, upon a nanomaterial, can induce Ostwald ripening via a purging of the grain-boundaries to facilitate single nanocrystals from polycrystalline precursors\cite{50}. Specifically, under high levels of stress - of the order of GPa - the material deformed plastically along the grain-boundary planes. We propose that ball milling can facilitate such high uniaxial stress and induce plastic deformation upon the sample to purge grain-boundaries from the material. We note that ball milling has been shown to induce pressures in the GPa-range\cite{34}. The pressures occurring during ball milling employing the ball mill and milling conditions used in this study have been calculated to be around 0.4 GPa\cite{61}. Moreover, the stresses associated with impacts between the balls and the sample are likely to be even higher.

We propose that the milling process might provide many localized anti-site defect repair attempts. Since point defects increase the brittleness of a material, it seems likely that defect rich regions are preferentially brought back to the surface.

We note that Prochowicz et al.\cite{20} reported low defect levels in mechanochemically prepared perovskite-type CH$_3$NH$_3$Pbl$_3$. Thus, a similar mechanism might have played a role in their synthesis.

Conclusions

We have simulated the crystallization of Ba$_3$SrxLiF$_3$ under conditions that mirror an impact event during mechano synthesis using a high energy ball mill. The simulations revealed that during crystallization, Ba-Li anti-site defects are formed, increasing the ionic mobility in their vicinity. Also the replacement of (a part of the) Ba ions by Sr ions increases the ion mobility considerably as shown by simulation and experiment. Both, experiment and simulation also revealed both ion species, F and Li, to be mobile in BaLiF$_3$. The lower ionic mobility in mechanosynthesized BaLiF$_3$ compared to thermally prepared BaLiF$_3$ was attributed to a lower defect density. This might be caused by contamination during the thermal treatments, or it could be facilitated by the mechano synthesis technique, which repeatedly exposes anti-site defects to surfaces where they can be eliminated. If this assumption turns out to be correct, which remains to be tested in future work, it seems likely, that this process also occurs in other layered systems in which multiple ion species compete for sites during crystallization.

Supporting information

The Supporting Information is available free of charge on the ACS Publications website.

Interatomic potential parameters, further molecular graphics, further $^{19}$F and $^{7}$Li MAS NMR spectra, static $^{7}$Li NMR spectra, Arrhenius plot of the dc conductivities. Videos showing the crystallization and the F ion mobility near an anti-site defect.
Synopsis

MD Simulation of the crystallization of $\text{Ba}_{1-x}\text{Sr}_x\text{LiF}_3$ showed the formation of Ba-Li anti-site defects, which increase the mobility of F and Li ions in their vicinity. Synthesis of $\text{BaLiF}_3$ by ball milling seems to decrease the density of this defect-type compared to thermally prepared $\text{BaLiF}_3$ presumably by exposing the defects to the crystallite surface where they can be repaired.
