#### ABSTRACT

In current theories of language comprehension, people routinely and implicitly predict upcoming words by pre-activating their meaning, morpho-syntactic features and even their specific phonological form. To date the strongest evidence for phonological prediction comes from a landmark 2005 Nature Neuroscience publication by DeLong, Urbach and Kutas, who observed a graded modulation of electrical brain potentials (N400) to nouns and preceding articles by the probability that people use a word to continue the sentence fragment ('cloze'). In a direct replication study spanning 9 laboratories (N=334), we failed to replicate the crucial article-elicited N400 modulation by cloze, while we successfully replicated the commonlyreported noun-elicited N400 modulation. We observed this pattern of failure and success in a pre-registered replication analysis, a pre-registered single-trial analysis, and exploratory Bayesian analyses. Contra the strong prediction view in which people routinely pre-activate the phonological word-form, our results suggest a more limited role for prediction during language comprehension.

#### 1 INTRODUCTION

2 In the last decades, the idea that people routinely and implicitly predict upcoming 3 words during language comprehension turned from a highly controversial hypothesis to a 4 widely accepted assumption. Initial objections to prediction in language were based on a lack 5 of empirical support (e.g., Zwitserlood, 1989), incompatibility with traditional bottom-up 6 models and contemporary interactive models of language comprehension (e.g., Kintsch, 7 1988; Marslen-Wilson & Tyler, 1988), and the purported futility of prediction in a generative 8 system where sentences can continue in infinitely many different ways (Jackendoff, 2002). 9 Current theories of language comprehension, however, reject such objections and posit 10 prediction as an integral and inevitable mechanism by which comprehension proceeds 11 quickly and incrementally (e.g., Altmann & Mirkovic, 2009; Dell & Chang, 2014; Pickering 12 & Garrod, 2013). Prediction, i.e., context-based pre-activation of an upcoming linguistic 13 input, is thought to occur at all levels of linguistic representation (semantic, morpho-syntactic 14 and phonological/orthographic) and serves to facilitate the integration of newly available 15 bottom-up information into the unfolding sentence- or discourse-representation. In this line of 16 thought, language is yet another domain in which the brain acts as a prediction machine 17 (Clark, 2013; Van Berkum, 2010; see also Friston, 2005, 2010; Summerfield & De Lange, 18 2014), hard-wired to continuously match sensory inputs with top-down, grammatical or 19 probabilistic expectations based on context and memory.

What promoted linguistic prediction from outlandish and deeply contentious to ubiquitous and somewhat anodyne? One of the key and most compelling pieces of empirical evidence for linguistic prediction to date comes from a landmark Nature Neuroscience publication by DeLong, Urbach and Kutas (2005), whose approach exploited a phonological rule of English whereby the indefinite article is realized as a before consonant-initial words and as an before vowel-initial words. In their experiment, participants read sentences of

26 varying degree of contextual constraint that led to expectations for a particular consonant- or 27 vowel-initial noun. This expectation was operationalized as a word's cloze probability 28 (cloze), calculated in a separate, non-speeded sentence completion task as the percentage of 29 continuations of a sentence fragment with that word (Taylor, 1953). For example, the sentence fragment "The day was breezy so the boy went outside to fly..." is continued with 30 'a' by 86% of participants, and "The day was breezy so the boy went outside to fly a...", it is 31 32 continued with 'kite' by 89% of participants. In the main experiment, word-by-word sentence 33 presentation enabled DeLong and colleagues to examine electrical brain activity elicited by 34 articles that were concordant with the highly expected but yet unseen noun ('a', followed by 35 'kite'), or by articles that were incompatible with the highly expected noun and heralded a less expected one ('an', followed by 'airplane'). The dependent measure was the amplitude of 36 37 the N400<sup>1</sup> event-related potential (ERP), a negative ERP deflection that peaks approximately 38 400 ms after word onset and is maximal at centroparietal electrodes (Kutas & Hillyard, 1980). The N400 is elicited by every word of an unfolding sentence and its amplitude is 39 40 smaller (less negative) with increasing ease of semantic processing (Kutas & Hillvard, 1984). 41 DeLong et al. found that the N400 amplitude for a given word decreased as a function of 42 increasing cloze probability, both for nouns and, critically, for articles. The systematic, 43 graded N400 modulation by article-cloze was taken as strong evidence that participants 44 activated the nouns in advance of their appearance, and that the disconfirmation of this

<sup>&</sup>lt;sup>1</sup> In this article, we use "N400 amplitude" as a shorthand for "ERP amplitude in the time window associated with the N400"; this ERP amplitude is actually a sum of the N400 ERP component and other ERP components (reflecting other aspects of cognition) that overlap with it in time and space.

45 prediction by the less-expected articles resulted in processing difficulty (higher N40046 amplitude at the article).

47 The results obtained with this elegant design warranted a much stronger conclusion 48 than related results available at the time. Previous studies that employed a visual-world 49 paradigm had revealed listeners' anticipatory eye-movements towards visual objects on the 50 basis of probabilistic or grammatical considerations (e.g., Altmann & Kamide, 1999). 51 However, predictions in such studies are scaffolded onto already-available visual context, and 52 therefore do not measure purely pre-activation, but perhaps re-activation of word information 53 previously activated by the visual object itself (Huettig, 2015). DeLong and colleagues 54 examined brain responses to information associated with concepts that were not pre-specified and had to be retrieved from long-term memory 'on-the-fly'. Furthermore, DeLong and 55 56 colleagues were the first to muster evidence for highly specific pre-activation of a word's 57 phonological form, rather than merely its semantic (e.g., Federmeier & Kutas, 1999) or 58 morpho-syntactic features (e.g., Van Berkum, Brown, Zwitserlood, Kooijman & Hagoort, 59 2005; Wicha, Moreno & Kutas, 2004). Crucially, as their demonstration involved 60 semantically identical articles (function words) rather than nouns or adjectives (content words) that are rich in meaning, the observed N400 modulation by article-cloze is unlikely to 61 62 reflect difficulty interpreting the articles themselves. Most notably, DeLong and colleagues 63 were the first to examine brain activity elicited by a range of more- or less-predictable 64 articles, not simply most-versus least-expected. Based on the observed correlation, they 65 argued that pre-activation is not all-or-none and limited to highly constraining contexts, but occurs in a graded, probabilistic fashion, with the strength of a word pre-activation 66 67 proportional to its cloze probability. Moreover, they concluded that prediction is an integral 68 part of real-time language processing and, most likely, a mechanism for propelling the 69 comprehension system to keep up with the rapid pace of natural language.

70 DeLong et al.'s study has had an immense impact on psycholinguistics,

71 neurolinguistics and beyond. It is cited by authoritative reviews (e.g., Altmann & Mirkovic, 72 2009; Hagoort, 2017; Lau, Phillips & Poeppel, 2008; Pickering & Clark, 2014; Pickering & 73 Garrod, 2007) as delivering decisive evidence for probabilistic prediction of words all way up 74 to their phonological form. Moreover, as a demonstration of pre-activation of phonological 75 form (sound) during reading, it is often cited as evidence for 'prediction through production' 76 (e.g., Pickering & Garrod, 2013), the hypothesis that linguistic predictions are implicitly 77 generated by the language production system. To date, DeLong et al. has received a total of 78 735 citations (Google Scholar), averaging to more than 1 citation per week over the past 79 decade, with an increasing number of citations in each subsequent year. The results also 80 played an important role in settling an ongoing debate in the neuroscience of language. It 81 provided the clearest evidence that the N400 component, which for 25 years had been taken 82 to directly index the high-level compositional processes by which people integrate a word's 83 meaning with its context (Brown & Hagoort, 1993; Chwilla, Brown & Hagoort, 1995; 84 Connolly & Phillips, 1994; Friederici, Steinhauer & Frisch, 1999; Van Berkum, Hagoort & 85 Brown, 1999; Van Petten, Coulson, Rubin, Plante, & Parks, 1999), actually reflected non-86 compositional processes by which word information is accessed as a function of context. 87 But how robust are gradient effects of form prediction? In over a decade that has 88 passed since the publication by DeLong and colleagues, there is still no published study that 89 directly replicates their graded pattern of results (for an overview, see Ito, Martin & 90 Nieuwland, 2017b). An alternative analysis of the same data by the authors did not yield a 91 statistically significant result (DeLong, 2009), but was not mentioned in the published report. 92 In at least three other unpublished data sets (DeLong, 2009; Miyamoto, 2016), DeLong and 93 colleagues did not find a significant correlation between article-N400 and cloze probability.

94 Martin, Thierry, Kuipers, Boutonnet, Foucart and Costa (2013) reported a successful

95 conceptual replication in native speakers of English but not in bilinguals. However, their 96 study did not test for a graded effect of cloze, and differed from the original in many crucial 97 aspects of the experimental design, data-preprocessing and statistical analysis, clouding both 98 a qualitative and quantitative comparison to the original results. Moreover, two attempts to 99 replicate the Martin et al. results in English monolinguals failed to yield a reliable effect of 100 cloze on article-ERPs (Ito, Martin & Nieuwland, 2017a,b).

101 As the tremendous scientific impact of the DeLong et al. findings is at odds with the 102 apparent lack of replication attempts, we report here a direct replication study. Inspired by 103 recent demonstrations for the need for large subject-samples in psychology and neuroscience 104 research (Button et al., 2013; Open Science Collaboration, 2015), our replication spanned 9 105 laboratories each with a sample size equal to or greater than that of the original. In addition to 106 duplicating the original analysis, our replication attempt also seeks to improve upon DeLong 107 et al.'s data analysis. DeLong et al.'s original analysis reduced an initial pool of 2560 data 108 points (32 subjects who each read 80 sentences) to 10 grand-average values, by averaging 109 N400 responses over trials within 10 cloze probability decile-bins (cloze 0-10, 11-20, et 110 cetera), per participant and then averaging over participants, even though these bins held 111 greatly different numbers of observations (for example, the 0-10 cloze bin contained 37.5% 112 of all data). These 10 values were correlated with the average cloze value per bin, yielding 113 numerically high correlation coefficients with large confidence intervals (for example, the Cz 114 electrode showed a statistically significant r-value of 0.68 with a 95% confidence interval 115 ranging from 0.09 to 0.92). However, this analysis potentially compromises power by 116 discretizing cloze probability into deciles and not distinguishing various sources of subject-, 117 item-, bin-, and trial-level variation. Furthermore, treating subjects as fixed rather than 118 random factor potentially inflates false positive rates, since the overall cloze effect is

confounded with by-subject variation in the effect (Barr, Levy, Scheepers & Tily, 2013;
Clark, 1973).

121 In our replication study, we followed two pre-registered analysis routes: a replication 122 analysis that duplicated the DeLong et al. analysis, and a single-trial analysis that modelled 123 variance at the level of item and subject. The effect of cloze on noun-elicited N400s (DeLong 124 et al., 2015; Kutas & Hillyard, 1984) is a necessary but not sufficient evidence for the claim 125 on pre-activation in language processing (as it is also compatible with the view that the 126 noun's cloze probability correlates with the ease of integration of that noun into the context). 127 It serves as a manipulation check to ensure that the experiment is able to successfully detect 128 graded variation in N400 amplitude, but does not provide strong evidence for the prediction 129 of phonological form. That evidence would come from the ERPs elicited by articles. 130 Observing a reliable effect of cloze on article-elicited N400s in the replication analysis and, 131 in particular, in the single-trial analysis, would constitute powerful evidence for the pre-

132 activation of phonological form during reading.

133

#### 134 **RESULTS**

We first obtained offline cloze probabilities for all target articles and nouns from a group of native English speakers. These values closely resembled those of the original study (see Methods for details). In the subsequent ERP experiment, a different group of participants (N=334) read the sentences word-by-word from a computer display at a rate of 2 words per second while we recorded their electrical brain activity at the scalp. The replication analysis and single-trial analysis described below were each pre-registered at https://osf.io/eyzaq/.

#### 141 **Replication analysis**

We sorted the articles and nouns into 10 bins based on each word's cloze probability
(e.g., items with 0-10% cloze were put in one bin, 10-20% in another, etc.). For each

144 laboratory, we averaged ERPs per bin first within, then across, participants. No baseline correction was used, following the procedure described in the Methods section in DeLong et 145 146 al (2005). We then correlated the averaged cloze values per bin with mean ERP amplitude in 147 the N400 time window (200-500 ms) elicited by the nouns (for the noun analysis) or articles 148 (for the article analysis) from the corresponding bin, yielding a Pearson correlation coefficient (r-value) per EEG channel. This analysis yielded a very different pattern than DeLong et al. 149 150 observed (Fig. 1). In no laboratory did article-N400 amplitude at centro-parietal sites become 151 significantly smaller (less negative) as article-cloze probability increased (in fact, in most 152 laboratories the pattern went into the opposite direction). Only in one laboratory (Lab 2) did 153 the correlation coefficient have a p-value below .05 in the predicted direction (positive) at 154 any electrode (uncorrected for multiple comparisons), but this effect was observed at a few 155 left-frontal electrodes, not at the central-parietal electrodes where DeLong et al found their 156 N400 effects. Moreover, in two laboratories (Labs 3 and 5), a statistically significant effect 157 was observed in the opposite direction, larger (more negative) article-N400 amplitude for 158 articles with increasing cloze probability. For the nouns, the pattern was more similar to the 159 DeLong et al. results. In six laboratories (Lab 2, 3, 4,6, 7, and 9), noun-N400 amplitude for 160 nouns at central-parietal or parietal-occipital electrodes became smaller with increasing noun-161 cloze, and in two other laboratories (Lab 5 and 8) the effects clearly went in the expected 162 direction without reaching statistical significance.

DeLong et al. recently mentioned using a 500 ms baseline correction procedure that was not mentioned in the published study (personal communication by DeLong, March 2017). In an exploratory analysis, we therefore recomputed the correlations based on data pooled from all laboratories using this baseline correction procedure (Fig 2.). This analysis also showed a lack of statistically significant positive correlations for the articles, but statistically significant positive correlations for the nouns. In exploratory Bayesian analyses

reported below, we perform an analysis to establish whether these results are consistent with
the size and direction of the effects reported by DeLong et al., regardless of statistical
significance.

172

#### 173 Single-trial analysis

174 We first performed baseline correction by subtracting the average amplitude in the 100 175 ms time window before word onset. Baseline-corrected ERPs for relatively expected and unexpected words and difference waveforms are shown in Fig. 3. Then, for the data pooled 176 177 across all laboratories, we used linear mixed effects models to regress the N400 amplitude (in 178 a spatiotemporal region of interest selected a priori based on the DeLong et al. results) on 179 cloze probability. For the articles, the effect of cloze was not statistically significant at the  $\alpha$ =.05 level,  $\beta$  = .29, CI [-.08, .67],  $\chi^2(1) = 2.31$ , p = .13 (see Fig. 4, left panel)<sup>2</sup>, with  $\beta$ 180 referring to the N400 difference in microvolts associated with stepping from 0% to 100% 181 182 cloze. The effect of cloze on N400 amplitude at the article did not significantly differ between laboratories,  $\chi^2(8) = 7.90$ , p = .44. For the nouns, however, higher cloze values were 183 strongly associated with smaller N400s,  $\beta = 2.22$ , CI [1.76, 2.69],  $\chi^2(1) = 56.50$ , p < .001 (see 184 Fig. 4, right panel). This pattern did not significantly differ between laboratories,  $\chi^2(8) =$ 185 11.59, p = .17. The effect of cloze on noun-N400s was statistically different from its effect on 186 article-N400s,  $\chi^2(1) = 31.38$ , p < .001. 187 Exploratory (i.e., not pre-registered) single-trial analyses 188

189 The effect of article-cloze did not significantly vary as a function of subject

190 comprehension question accuracy,  $\chi^2(1) = 0.45$ , p = .50. In addition, the effect of article-cloze

<sup>&</sup>lt;sup>2</sup> Unless otherwise indicated, p-values are two-tailed, and CIs are two-tailed 95% confidence intervals.

191 was also not statistically significant when subject comprehension accuracy was included in the analysis (100 ms baseline:  $\beta = .24$ , CI [-.17, .64],  $\chi^2(1) = 1.27$ , p = .26). 192 In our dataset, an analysis in the 500 to 100 ms time window before article-onset revealed 193 194 a non-significant effect of cloze that resembled the pattern observed after article-onset,  $\beta =$ .16, CI [-.07, .39],  $\gamma^2(1) = 1.82$ , p = .18. This suggested that a 500 ms baseline correction 195 procedure, which was used but not reported in DeLong et al. (2005), would better correct for 196 197 pre-article voltage-levels. We repeated our analysis with the 500 ms baseline correction procedure, the initially observed effect of article-cloze was numerically smaller and less 198 199 significant than it was in the pre-registered analysis ( $\beta = .14$ , CI [-.25, .53],  $\chi^2(1) = 0.46$ , p = 200 .50).

201

#### 202 Exploratory Bayesian analyses

203 For the articles, our pre-registered replication analyses yielded non-significant p-204 values, indicating failure to reject the null-hypothesis that cloze has no effect on N400 205 activity. To better adjudicate between the null-hypothesis (H<sub>0</sub>) and an alternative hypothesis 206 (H<sub>r</sub>), we performed exploratory replication Bayes factor analysis for correlations 207 (Wagenmakers, Verhagen & Ly 2016). The obtained replication Bayes factor quantifies the 208 evidence that there is an effect in the size and direction reported by DeLong et al. (see Fig. 5). 209 For the articles, this yielded strong to extremely strong evidence for the null hypothesis that 210 the effect of cloze is zero, with BF<sub>0r</sub> values up to 154 (at the Cz electrode depicted by 211 DeLong et al.,  $BF_{0r} = 77$ ), and strongest evidence at the posterior channels. For the nouns, we 212 obtained extremely strong evidence for the alternative hypothesis that the effect is nonzero, 213 particularly at posterior channels, with  $BF_{10}$  values up to 9,163,515 (at Cz,  $BF_{r0} = 10,725$ ). 214 The pattern of results was similar when the 500 ms pre-stimulus baseline was applied.

215 Next, we computed Bayesian mixed-effect model estimates ( $\beta$ ) and 95% credible 216 intervals (CrI) for our single-trial analyses, using priors based on the results from DeLong et 217 al. In both of our article-analyses credible intervals included zero (100 ms baseline:  $\beta = .31$ , 218 CrI [-.06.69]; 500 ms baseline:  $\beta = .17$ , CrI [-.22.55]). For the nouns, zero was not within 219 the credible interval:  $\beta = 2.24$ , CrI [1.77 2.70]. These Bayesian analyses further demonstrate 220 our failure to replicate the DeLong et al. article-effect alongside a successful replication of 221 the noun-effect. The analyses suggest that the data (combined with prior assumptions about 222 the effect) are not very consistent with the hypothesis that the article-effect is zero (further 223 information and posterior summaries are available in Supplementary Figure 2), but also are 224 extremely inconsistent with the hypothesis that the article-effect is as big as that observed by 225 DeLong and colleagues (2005). The data are most consistent with an effect that is more likely 226 to be positive than zero or negative, but is very small (so small that it was not detected at 227 traditional significance levels in this large-scale experiment with substantially higher power 228 than previous experiments).

229

#### 230 **Control experiment**

231 Lack of a statistically significant, article-elicited prediction effect could reflect a 232 general insensitivity of our participants to the phonologically conditioned variation of the 233 English indefinite article, i.e., a/an alternation. We ruled out this alternative explanation in an 234 additional experiment that followed the replication experiment as part of the same 235 experimental session. Participants read 80 short sentences containing the same nouns as the 236 replication experiment, preceded by a phonologically licit or illicit article (e.g., "David found 237 a/an apple..."), presented in the same manner as before. In each laboratory, nouns following 238 illicit articles elicited a late positive-going waveform compared to nouns following licit 239 articles (see Fig. 6), starting at about 500 ms after word onset and strongest at parietal

electrodes. This standard P600 effect (Osterhout & Holcomb, 1992) was confirmed in a single-trial analysis,  $\chi^2(1) = 83.09$ , p < .001, and did not significantly differ between labs,  $\chi^2(8) = 8.98$ , p = .35.

#### 243 **DISCUSSION**

244 In a landmark study, DeLong, Urbach and Kutas observed a statistically significant, 245 graded modulation of article- and noun-elicited electrical brain potentials (N400) by the pre-246 determined probability that people continue a sentence fragment with that word (cloze). They 247 concluded that people routinely and probabilistically pre-activate upcoming words to a high 248 level of detail, including whether a word starts with a consonant or vowel. Our direct 249 replication study spanning 9 laboratories successfully replicated a statistically significant 250 effect of cloze on noun-elicited N400 activity but, critically, failed to replicate such an effect 251 of cloze on article-elicited N400 activity. This pattern of success and failure was observed in a pre-registered replication analysis that duplicated the original study's analysis, and a pre-252 253 registered single-trial analysis that modelled variance at the level of item and subject. 254 Exploratory Replication Bayes Factor analyses confirmed that we successfully replicated the 255 direction and size of the correlations reported by Delong et al. for the nouns, but not for the 256 articles. Exploratory Bayesian mixed-effects model analyses suggested that, while there is 257 some evidence that the true population-level effect may be in the direction reported by DeLong and colleagues, the effect is likely far smaller than what they reported. In fact, the 258 259 effect is likely is too small to be meaningfully observed without very large sample sizes, 260 hence of uncertain theoretical interest. Finally, a control experiment confirmed that our 261 participants did respect the phonological alternation a/an of the article with nouns used in the 262 replication experiment.

263 Our findings carry important theoretical implications by challenging a crucial cornerstone of the 'strong prediction view' held by current theories of language comprehension (e.g., 264 265 Altmann & Mirkovic, 2009; Pickering & Garrod, 2013). The strong prediction view entails 266 two key claims. The first is that people pre-activate words at all levels of representation in a routine and implicit (i.e., non-strategic) fashion. Pre-activation is not limited to a word's 267 268 meaning, but includes its grammatical features and even its orthographic and/or phonological 269 form. This would put language on a par with other cognitive systems such as visual 270 perception that attempt to predict the inputs to lower-level ones (Friston, 2005, 2010; 271 Summerfield & De Lange, 2014). The second claim is that pre-activation occurs at all levels 272 of contextual support and gradually increases in strength with the level of contextual support. When contextual support for a specific word is high, like at a 100% cloze value, the word's 273 274 form and meaning is strongly pre-activated. When contextual support for a word is low, like 275 when it is one amongst 20 words each with a 5% cloze value, pre-activation is distributed 276 across multiple potential continuations. However, even then, a word's form and meaning are 277 pre-activated, just weakly so. The strength of pre-activation is probabilistic, that is, linked to 278 estimated probability of occurrence.

279 DeLong and colleagues, and subsequently other scientists (e.g., Dell & Chang, 2014; Pickering & Clark, 2013), took their results as the evidence to support both these claims. 280 281 DeLong et al (2005) was – and still is - the only study to date that measured pre-activation at 282 the prenominal articles a and an that do not differ in their semantic or grammatical content, 283 and that observed a graded relationship between cloze and N400 activity across a range of 284 low- and high-cloze words, rather than merely a difference between low- and high-cloze 285 words. Given that the use of these articles depends on whether the next word starts with a 286 vowel or consonant, their results were considered as powerful evidence that participants 287 probabilistically pre-activated the initial sound of upcoming nouns.

288 However, we show that there is no statistically significant effect of cloze on article-289 elicited N400 activity, using a sample size more than ten times that of the original, and a 290 statistical analysis that better accounts for sources of non-independence than the original 291 averaging-based correlation approach. If an effect of cloze on article-N400s exists at all, its 292 true effect size is so small that it cannot be reliably detected even in an expansive multi-293 laboratory approach, let alone in the typical sample size in psycholinguistic and 294 neurolinguistic experiments (roughly, N= 30). This means that even if article-cloze is 295 associated with a graded modulation of N400 amplitudes, this effect seems to be so small that 296 it cannot be reliably measured with small samples, and thus the previous studies may not 297 have contributed much reliable information to our understanding of this effect. Moreover, it 298 is also possible that the effect is sensitive to specifics of the experimental procedure and 299 context that it lacks generalizability. Current theoretical positions thus either require new 300 strong evidence for phonological pre-activation or require revision. In particular, the strong 301 prediction view that claims that pre-activation routinely occurs across all – including 302 phonological – levels (Pickering & Garrod, 2013), can no longer be viewed as having strong 303 empirical support. Our work impels the field think differently about what constitutes strong 304 evidence within a theory, but also highlights the need for a theory of linguistic prediction to 305 formulate quantitative predictions about the effect-size of to-be-observed effects. 306 By contrast, we observed a strong and statistically significant effect of cloze on noun-

elicited activity in the majority of our analyses. Although three of the nine laboratories did not show statistically significant correlations between noun-cloze and N400s, data pooled all laboratories showed a strong and statistically significant noun-cloze effect, our Replication Bayes Factor analysis overwhelmingly replicated the direction and size of the noun-cloze effect of DeLong et al., and our more powerful single-trial analysis revealed a significant noun-cloze effect in each of the laboratories. These results are therefore consistent with the

handful of studies that reported a graded relationship between noun-cloze and noun-N400s
(DeLong et al., 2005; Kutas & Hillyard, 1984; Wlotko & Federmeier, 2012).

315 Where does this pattern of failure and success leave the strong prediction view? 316 Following the experimental logic of DeLong et al, we do not have sufficient evidence to 317 conclude that people routinely pre-activate the initial phoneme of an upcoming noun, or 318 perhaps any other word form information. Without pre-activation of the initial phoneme, the 319 specific instantiation of the article does not cause people to revise their prediction about the 320 meaning of the upcoming noun, thus lacking any impact on processing. Crucially, this 321 conclusion is incompatible with the strong prediction view, because it suggests that preactivation does not occur to the level of detail that is often assumed. Our results are also 322 323 incompatible with an alternative interpretation of the DeLong et al. findings that people 324 predict the article itself together with the noun (Ito, Corley, Pickering, Martin & Nieuwland, 325 2016; Van Petten & Luka, 2012), and they pose a serious challenge to the theory that comprehenders predict upcoming words, including their initial phonemes, through implicit 326 327 production (Pickering & Garrod, 2013). Crucially, the idea that prediction is probabilistic, 328 rather than all-or-none, is now questionable, given that there is no other published report of a 329 pre-activation gradient. Although other studies have claimed prediction of form (Ito et al., 330 2016) or a prediction gradient (Smith & Levy, 2013), no study has indisputably demonstrated 331 graded pre-activation, i.e., graded effects occurring before the noun. Effects that are observed 332 upon, rather than before the noun, do not purely index pre-activation but index a mixture of 333 memory retrieval and semantic integration processes instigated by the noun itself (Baggio & 334 Hagoort, 2011; Lau, Namyst, Fogel & Delgado, 2016; Otten & Van Berkum, 2008; Steinhauer, Royle, Drury & Fromont, 2017). Therefore, there is currently no clear evidence to 335 336 support routine probabilistic pre-activation of a noun's phonological form during sentence 337 comprehension.

338 Our results, however, do not necessarily exclude phonological form pre-activation, and 339 we temper our conclusion with a caveat stemming from the a/an manipulation. For this 340 manipulation to 'work', people must specifically predict the initial phoneme of the next word, 341 and revise this prediction when faced with an unexpected article. However, because articles 342 are only diagnostic about the next word within the noun phrase, rather than about the head 343 noun itself, an unexpected article does not refute the upcoming noun, it merely signals that 344 another word would come first (e.g., 'an old kite'). This opens up explanations for why the 345 a/an manipulation 'fails'. In addition, comprehenders may not predict the noun to follow 346 immediately, but at a later point; the unexpected article then does not evoke a change in 347 prediction. Predictions about a specific position may be disconfirmed too often in natural 348 language to be viable. This idea is supported by corpus data (Corpus of Contemporary 349 American English and British National Corpus,), showing a mere 33% probability that a/an is 350 directly followed by a noun. Alternatively, people predict the noun to come next, but only 351 revise their prediction about its linear position while retaining the prediction about its 352 meaning. So perhaps a revision of the predicted meaning, not the position, is required to 353 trigger differential ERPs. In both of these hypothetical scenarios, people do not revise their 354 prediction about the upcoming noun's meaning unless they must.

355 Our results can be straightforwardly reconciled with effects reported for other pre-356 nominal manipulations, such as those of Dutch or Spanish article-gender (e.g., Van Berkum 357 et al., 2008; Otten, Nieuwland & Van Berkum, 2008; Otten & Van Berkum, 2009; Wicha et 358 al., 2004). Unlike a/an articles, gender-marked articles can immediately disconfirm the noun, 359 because article- and noun-gender agrees regardless of intervening words (e.g., the Spanish 360 article 'el' heralds a masculine noun). Revising the prediction about the noun presumably 361 results in a semantic processing cost, thereby modulating N400 activity. Although gender-362 marked articles do not consistently incur the exact same type of effect and have only been

observed at very high cloze values, previous studies suggest that a noun's grammatical
gender can be pre-activated along with its meaning. Compared to this gender-manipulation,
DeLong et al's study based on the English a/an manipulation claimed a stronger version of
the prediction view, namely that people predict which word comes next up to its phonological
form and, make backwards prediction as to the phonological form of the preceding linguistic
material even on the basis of probabilistic, graded information.

369 What do our results say about prediction during natural language processing? Like the 370 conclusions by DeLong et al., ours are limited by the generalization from language 371 comprehension in a laboratory setting. On one hand, a rich conversational or story context 372 may enhance predictions of upcoming words, and listeners may be more likely to pre-activate the phonological form of upcoming words than readers. On the other hand, our laboratory 373 374 setting offered particularly good conditions for prediction of the next word's initial sound to 375 occur. Each article was always immediately followed by a noun, unlike in natural language. 376 Moreover, compared to natural reading rates our word presentation rate was slow, which may 377 facilitate predictive processing (Ito et al., 2016; Wlotko & Federmeier, 2015). In natural 378 reading, articles are hardly fixated and often skipped (e.g., O'Regan 1979). In short, 379 arguments can be made both for and against phonological form prediction in natural language 380 settings, and novel avenues of experimentation are needed to settle this issue.

DeLong and colleagues recently stated an omission in the description of their data analysis, i.e., a baseline procedure was applied to the data but inadvertently omitted from the description (DeLong et al., 2005). We have shown that our conclusions hold regardless of the baseline procedure. In a recent commentary, Delong, Urbach, and Kutas (2017) also described filler-sentences in their experiment, which were omitted from their original report, and were neither provided nor mentioned to us by the authors upon our request for the stimuli. DeLong et al. used the existence of these filler-sentences to dismiss an alternative

388 explanation of their original findings, namely that an unusual experimental context wherein 389 every sentence contains an article-noun combination leads participants to strategically predict 390 upcoming nouns. Following this logic, we failed to replicate their article-effects despite an 391 experimental context that could inadvertently encourage strategic prediction (for 392 demonstrations of experimental context boosting predictive processing, see Brothers, Swaab 393 & Traxler, 2017; Lau, Holcomb & Kuperberg, 2013). Therefore, the presence of fillers in 394 their experiment versus absence in ours cannot straightforwardly explain the different results, 395 and may even strengthen our conclusions.

396 To conclude, we failed to replicate the main result of DeLong et al., a landmark study 397 published more than ten years ago that has not been directly replicated since. Our results 398 suggest that, if there is an effect of article-cloze probability on the amplitude of the N400, it 399 is too small and/or too sensitive to unknown experimental design factors to have been 400 meaningfully measured in previous small-sample-size experiments. We conclude that such an 401 effect does not constitute strong evidence for current theoretical positions on the importance 402 of prediction (e.g., Pickering & Garrod, 2013). Our findings thus challenge one of the pillars 403 of the 'strong prediction view' in which people routinely and probabilistically pre-activate information at all levels of linguistic representation, including phonological form information 404 405 such as the initial phoneme of an upcoming noun. Consequently, there is currently no 406 convincing evidence that people pre-activate the phonological form of an upcoming noun 407 during sentence comprehension, and we take our findings to suggest a more limited role for 408 prediction during language comprehension. In addition, our findings further highlight the 409 importance of direct replication, large sample size studies, transparent reporting and of pre-410 registration to advance reproducibility and replicability in the neurosciences.

#### 411 MATERIALS AND METHODS

412 Experimental design and materials. Nieuwland twice requested all original 413 materials from DeLong et al., including the questions and norms, with the stated purpose of 414 direct replication (personal communication, November 4 and 19, 2015), upon which DeLong 415 et al. made available the 80 sentences described in the original study. These sentences were 416 then adapted from American to British spelling and underwent a few minor changes to ensure 417 their suitability for British participants. The complete set of materials and the list of changes 418 to the original materials are available online (Supplementary Table 1 and 2). The materials 419 were 80 sentence contexts with two possible continuations each: a more or less expected 420 indefinite article + noun combination. The noun was followed by at least one subsequent 421 word. All article + noun continuations were grammatically correct. Each article + noun 422 combination served once as the more expected continuation and the other time as the less 423 expected continuation, in different contexts. We divided the 160 items in two lists of 80 424 sentences such that each list contained each noun only once. Each participant was presented 425 with only one list (thus, each context was seen only once). One in four sentences was 426 followed by a yes/no comprehension question, which yielded a mean response accuracy of 95% (after taking into account ambiguity in three of the questions, see Supplemental Table 2 427 428 and 3). While this percentage is very similar to that reported by DeLong et al., we note that 429 this cannot be directly compared to the accuracy reported in DeLong et al., because we had to 430 create new comprehension questions in the absence of the original ones. Regardless, because 431 Delong et al. suggested that our results were due to poor language comprehension (DeLong, 432 Urbach & Kutas, 2017), we describe an exploratory analysis in which we attempt to account 433 for variation in response accuracy in the statistical model.

We obtained article cloze and noun cloze ratings from a separate group of nativespeakers of English who were students at the University of Edinburgh and did not participate

436 in the ERP experiment. They were instructed to complete the sentence fragment with the best 437 continuation that comes to mind (Taylor, 1953). We obtained article cloze ratings from 44 438 participants for 80 sentence contexts truncated before the critical article. Noun cloze ratings 439 were obtained by first truncating the sentences after the critical articles, and presenting two 440 different, counterbalanced lists of 80 sentences to 30 participants each, such that a given 441 participant only saw each sentence context with the expected or the unexpected article. The 442 obtained values closely resemble those of the original study, with the same range (0-100% for 443 articles and nouns), slightly lower median values (for articles and nouns, 29% and 40%, 444 compared to 31% and 46% in the original study), but slightly higher mean values (for articles 445 and nouns, 41% and 46%, compared to 36% and 44%). Because the sentence materials we 446 used describe common situations that can be understood by any English speaker, and because 447 students at the University of Edinburgh come from across the whole of the UK, we had no a 448 priori expectation that cloze ratings would differ substantially across laboratories, and thus 449 we did not obtain cloze norms from other sites. Consistent with this assumption, nothing in 450 our results suggests stronger cloze effects in University of Edinburgh students compared to 451 other students, suggesting that our cloze norms are sufficiently representative for the other 452 universities.

453 Participants. Participants were students from the University of Birmingham, Bristol, 454 Edinburgh, Glasgow, Kent, Oxford, Stirling, York, or volunteers from the participant pool of 455 University College London or Oxford University, who received cash or course credit for 456 taking part in the ERP experiment. Participant information and EEG recording information 457 per laboratory is available online (Supplementary Table 3). We pre-registered a target sample 458 size of 40 participants per laboratory, which was thought to give at least 32 participants (the 459 sample size of DeLong et al.) per laboratory after accounting for data loss, as was later 460 confirmed. Due to logistic constraints, not all laboratories reached an N of 40. Because in two

labs corruption of data was incorrectly assumed before computing trial loss, these
laboratories tested slightly more than 40 participants. All participants (N = 356; 222 women)
were right-handed, native English speakers with normal or corrected-to-normal vision,
between 18–35 years (mean, 19.8 years), free from any known language or learning disorder.
Eighty-nine participants reported a left-handed parent or sibling.

466 Procedure. After giving written informed consent, participants were tested in a single
467 session. Sentences were presented visually in the center of a computer display, one word at a
468 time (200 ms duration, followed by a blank screen of 300 ms duration<sup>3</sup>). Participants were
469 instructed to read sentences for comprehension and answer yes/no comprehension questions
470 by pressing hand-held buttons. The electroencephalogram (EEG) was recorded from at least
471 32 electrodes.

The replication experiment was followed by a control experiment, which served to detect sensitivity to the correct use of the a/an rule in our participants. Participants read 80 relatively short sentences (average length 8 words, range 5-11) that contained the same critical words as the replication experiment, preceded by a correct or incorrect article. As in

<sup>3</sup> Due to a programming error, in four labs (1, 3, 5 and 8, which used E-prime scripts) the critical articles and nouns, but not other words, were followed by a 380 ms blank instead of the intended 300 ms. However, this delay is unlikely to have affected the results because if it was noticed at all, which is unlikely, it appeared after the N400 window associated with the article. Moreover, if anything, longer duration facilitates language comprehension and predictive processing (Camblin, LeDoux, Boudewyn, Gordon & Swaab, 2007; Wlotko & Federmeier, 2015; Ito et al., 2016), making it more, not less likely to find an effect of cloze on the article-ERPs. Of note, the qualitative pattern of the results from the pre-registered single-trial analysis did not change when we removed these labs from the analysis.

the replication experiment, each critical word was presented only once, and was followed by
at least one more word. All words were presented at the same rate as the replication
experiment. There were no comprehension questions in this experiment. After the control
experiment, participants performed a Verbal Fluency Test and a Reading Span test; the
results from these tests are not discussed here. All stimulus presentation scripts are publicly
available in two different software packages (E-Prime and Presentation) on
https://osf.io/eyzaq.

483 Data processing. Data processing was performed in BrainVision Analyzer 2.1(Brain 484 Products, Germany). We performed one pre-registered replication analysis that followed the 485 DeLong et al. analysis as closely as possible and one pre-registered single-trial analysis (Open Science Framework, https://osf.io/eyzaq). All non-pre-registered analyses are 486 487 considered as exploratory. First, we interpolated bad channels from surrounding channels, 488 and downsampled to a common set of 22 EEG channels per laboratory which were similar in 489 scalp location to those used by DeLong et al. One laboratory did not have 12 of the selected 490 22 channels in its EEG channel montage, and we matched the full 22-channel layout used for 491 other laboratories by creating 12 virtual channels from neighbouring channels using topographic interpolation by spherical splines. We then applied a 0.01-100 Hz digital band-492 493 pass filter (including 50 Hz Notch filter), re-referenced all channels to the average of the left 494 and right mastoid channels (in a few participants with a noisy mastoid channel, only one 495 mastoid channel was used), and segmented the continuous data into epochs from 500 ms 496 before to 1000 ms after word onset. We then performed visual inspection of all data segments 497 and rejected data with amplifier blocking, movement artifacts, or excessive muscle activity. 498 Subsequently, we performed independent component analysis (Jung et al., 2000) on a 1-Hz 499 high-pass filtered version of the data, and applied the obtained weightings to the original data 500 to correct for blinks, eye movements or steady muscle artefacts. After this, we automatically

rejected segments containing a voltage difference of over  $120 \,\mu V$  in a time window of 150ms or containing a voltage step of over  $50 \,\mu V/ms$ . Participants with fewer than 60/80 article trials or 60/80 noun trials were removed from the analysis, leaving a total of 334 participants (range across laboratories 32-42, and therefore each lab had a sample size at least as large as DeLong et al.). On average, participants had 77 article trials and 77 noun trials.

506 **Pre-registered replication analysis.** We applied a 4<sup>th</sup>-order Butterworth band-pass 507 filter at 0.2-15 Hz to the segmented data, averaged trials per participant within 10% cloze 508 bins (0-10, 11-20, etc. until 91-100), and then averaged the participant-wise averages 509 separately for each laboratory. Because the bins did not contain equal numbers of trials (the 510 intermediate bins contained fewest trials), like in DeLong et al., not all participants 511 contributed a value for each bin to the grand average per laboratory. For nouns and articles 512 separately, and for each EEG channel, we computed the correlation between ERP amplitude 513 in the 200-500 ms time window per bin with the average cloze probability per bin.

514 **Pre-registered single-trial analysis.** In this analysis, we did not apply the 0.2-15 Hz 515 band-pass filter, which carries the risk of inducing data distortions (Luck, 2014; Tanner, 516 Morgan-Short & Luck, 2015). However, we deemed it necessary to perform a baseline 517 correction of the data. This procedure corrects for spurious voltage differences before word 518 onset, generating confidence that observed effects are elicited by the word rather than 519 differences in brain activity that already existed before the word and is a standard procedure 520 in ERP research (Luck, 2014). DeLong et al (2005) did not report a baseline correction, nor 521 did any of the related work from DeLong and colleagues that was reported in DeLong (2009). 522 Yet baseline correction has been used in many other publications from the Kutas Cognitive 523 Electrophysiology Lab. We chose a 100 ms pre-stimulus baseline as the most frequently used 524 one both in other studies from Kutas lab and in similar studies from other labs. For each trial,

we performed baseline correction by subtracting the mean voltage of the -100 to 0 ms timewindow from each data point in the epoch.

527 Instead of averaging N400 data across trials and participants for subsequent statistical 528 analysis, we performed linear mixed effects model analysis (Baayen, Davidson & Bates, 2008) of the single-trial N400 data, using the "lme4" package (Bates, Maechler, Bolker & 529 530 Walker, 2014) in the R software (R CoreTeam, 2014). This approach simultaneously models 531 variance associated with each subject and with each item. Using a spatiotemporal region-of-532 interest approach based on the DeLong et al. results, our dependent measure (N400 533 amplitude) was the average voltage across 6 centro-parietal channels (Cz/C3/C4/Pz/P3/P4) in 534 the 200-500 ms window for each trial. Analysis scripts and data to run these scripts are 535 publicly available on https://osf.io/eyzaq.

536 For articles and nouns separately, we used a maximal random effects structure as justified 537 by the design (Barr et al., 2013), which did not include random effects for 'laboratory' as there were only 9 laboratories. Z-scored cloze was entered in the model as a continuous 538 539 variable, and laboratory was entered as a deviation-coded nuisance predictor. We tested the effects of 'laboratory' and 'cloze' through model comparison with a  $\chi^2$  log-likelihood test. 540 541 We tested whether the inclusion of a given fixed effect led to a significantly better model fit. 542 The first model comparison examined laboratory effects, namely whether the cloze effect 543 varied across laboratories (cloze-by-laboratory interaction) or whether the N400 magnitudes 544 varied over laboratory (laboratory main effect). If laboratory effects were nonsignificant, we 545 dropped them from the analysis because they were not of theoretical interest. For the articles 546 and nouns separately, we compared the subsequent models below. Each model included the 547 random effects associated with the fixed effect 'cloze' (see Barr et al., 2014). All output  $\beta$ estimates and 95% confidence intervals (CI) were transformed from z-scores back to raw 548

scores, and then back to the 0-100% cloze range, so that the voltage estimates represent the

550 change in voltage associated with a change in cloze probability from 0 to 100.

551 Model 1: N400 ~ cloze \* laboratory + (cloze | subject) + (cloze | item)

552 Model 2: N400 ~ cloze + laboratory + (cloze | subject) + (cloze | item)

553 Model 3: N400 ~ cloze + (cloze | subject) + (cloze | item)

554 Model 4: N400 ~ (cloze | subject) + (cloze | item)

555 In an analysis that included the data from both articles and nouns, we also tested the

differential effect of cloze on article ERPs and on noun ERPs by comparing models with and

557 without an interaction between cloze and the deviation-coded factor 'wordtype'

558 (article/noun). Random correlations were removed for the models to converge.

559 Model 1: N400 ~ cloze \* wordtype + (cloze \* wordtype || subject) + (cloze \* wordtype ||

560 item)

561 Model 2: N400 ~ cloze + wordtype + (cloze \* wordtype || subject) + (cloze \* wordtype ||
562 item)

563 **Exploratory correlation analysis.** Of note, DeLong et al. have recently described 564 using a 500 ms baseline correction procedure that they failed to mention in DeLong et al. 565 (2005). Using this baseline correction procedure, we recomputed the correlations that we 566 obtained in our Replication analysis. To compare our results most directly with those reported 567 in Figure 1C of DeLong et al. (2005), we pooled data from all the laboratories so that we 568 would have a single r-value for each EEG-channel.

569 **Exploratory single-trial analyses.** We performed an exploratory analysis in the 500 570 to 100 ms time window before the article, using the originally (-100 to 0 ms) baselined data, 571 using Model 3 and 4 from the article analysis. This window covers the first 400 ms of the 572 word that preceded the article. Analysis in this window yielded a similar pattern as in the pre-573 registered analysis, which indicates that a baseline correction procedure covering the entire

574 500 ms pre-stimulus window would account better for pre-article voltage levels. We 575 performed this additional analysis, the results of which did not change our conclusions and 576 are shown in Supplementary Figure 1.

577 We also performed an exploratory analysis in which we control for a potential influence of response accuracy, taken as a proxy for the subject's attention to the task, on 578 579 predictive processing of linguistic input. We entered the (z-transformed) average response 580 accuracy of each subject in our model, and compared the models below. Comparison of 581 Model 1 and 2 tested whether the effect of cloze on the article-N400s depended subject 582 accuracy. Comparison of Model 2 and 3 tested whether there was a significant effect of cloze 583 on article-N400s when subject accuracy was included in the model. 584 Model 1: N400 ~ accuracy \* cloze + (cloze | subject) + (cloze | item)

585 Model 2: N400 ~ accuracy + cloze + (cloze | subject) + (cloze | item)

586 Model 3: N400 ~ accuracy + (cloze | subject) + (cloze | item)

Exploratory Bayesian analyses. Supplementing the Replication analysis, we 587 588 performed a Replication Bayes factor analysis for correlations (Wagenmakers et al., 2016) 589 using as prior the size and direction of the effect reported in the original study. We performed 590 this test for each electrode separately, after collapsing the data points from the different 591 laboratories. Because we had no articles in the 40-50 % cloze bin, there was a total of 9 and 592 10 data points per laboratory for the articles and nouns, respectively. Our analysis used priors 593 estimated from the DeLong et al results matched as closely as possible to our electrode 594 locations. A Bayes factor between 3 and 10 is considered moderate evidence, between 10-30 595 is considered strong evidence, 30-100 is very strong evidence, and values over 100 are 596 considered extremely strong evidence (Jeffreys, 1961). In addition to using a 100 ms pre-597 stimulus baseline, we also computed the replication Bayes factors using the 500 ms pre-598 stimulus time window for baseline correction. Results are shown in Figure 5.

599 Supplementing the pre-registered single-trial analyses, we performed an exploratory 600 Bayesian mixed-effects model analysis using the brms package for R (Buerkner, 2016), 601 which fits Bayesian multilevel models using the Stan programming language (Stan 602 Development Team, 2016). Nieuwland requested to use the results of a mixed-effects model 603 reanalysis of the DeLong et al. data as an appropriate prior (personal communication from 604 Nieuwland, November 14 and 22 2017); this request was declined by DeLong and 605 colleagues. We were therefore limited to using a prior centered on a point estimate based on 606 the Delong et al. correlation analysis, namely our estimate of the observed effect size at Cz 607 for a difference between 0% cloze and 100% cloze (1.25  $\mu$ V and 3.75  $\mu$ V for articles and 608 nouns, respectively, based on visual inspection of the graphs) and a prior centered on zero for 609 the intercept. Both priors had a normal distribution and a standard deviation of 0.5 (given the 610 a priori expectation that average ERP voltages in this window generally fluctuate on the order 611 of a few microvolts; note that these units are expressed in terms of the z-scored cloze values, 612 rather than the original cloze values, such that  $\mu$  for the cloze prior was 0.45, which 613 corresponds to a raw cloze effect of 1.25). We computed estimates and 95% credible intervals 614 for each of the mixed-effects models we tested, and transformed these back into raw cloze 615 units. The credible interval is the range of values such that one can be 95% certain that it 616 contains the true effect, given the data, priors and the model. The results from these analyses 617 are shown in Supplementary Figure 2; the analyses suggest that, while there may be a small 618 positive association between article cloze and ERP amplitude elicited by the articles, the 619 effect is substantially smaller than that estimated by Delong and colleagues (2005) and likely 620 is too small to be meaningfully observed without very large sample sizes, hence of uncertain 621 theoretical interest.

622 Control experiment. Analysis of the control experiment involved a comparison
623 between a model with the categorical factor 'grammaticality' (grammatical/ungrammatical)

- and a model without. Our dependent measure (P600 amplitude; Osterhout & Holcomb, 1992)
- 625 was the average voltage across 6 centro-parietal channels (Cz/C3/C4/Pz/P3/P4) in the 500-
- 626 800 ms window for each trial. Results are shown in Figure 6.
- 627 Model 1: P600 ~ grammaticality + (grammaticality | subject) + (grammaticality | item)
- 628 Model 2: P600 ~ (grammaticality | subject) + (grammaticality | item)

#### Acknowledgements

This work was partly funded by ERC Starting grant 636458 to H.J.F.

#### **Competing financial interests**

791

Figure 1. Replication analysis. Correlations between N400 amplitude and article/noun cloze 792 793 probability per laboratory. N400 amplitude is the mean voltage in the 200-500 ms time 794 window after word onset. A positive value corresponds to the canonical finding that N400 amplitude became smaller (less negative-more positive) with increasing cloze probability. 795 796 Here and in all further plots, negative voltages are plotted upwards. Upper graph: Scatter 797 plots showing the correlation between cloze and N400 activity at electrode Cz, for each lab. The position of Cz and the other electrodes is displayed in the head plot in between the upper 798 799 and lower graph. Lower graph: Scalp distribution of the r-values for each lab. Asterisks (\*) indicate electrodes that showed a statistically significant correlation (two-tailed p < 0.05, not 800 801 corrected for multiple comparisons). Exact r- and p-values for each laboratory and EEG 802 channel are available on https://osf.io/eyzaq.

- Figure 2. Replication analysis. Scalp distribution and r-values at each channel based on data
- 806 pooled from all laboratories, using a 500 ms baseline correction procedure as used by
- 807 DeLong et al (2005). Asterisks (\*) indicate electrodes that showed a statistically significant
- 808 correlation (two-tailed, not corrected for multiple comparisons).

- 811 unexpected words (cloze higher/lower than 50%) and the associated difference waveforms
- 812 (low minus high cloze) at electrode Cz. Dotted lines indicate 1 standard deviation above or
- 813 below the grand average.

**Figure 4. Single-trial analysis.** Relationship between cloze and ERP amplitude for articles and nouns in the N400 spatiotemporal window, as illustrated by the mean ERP values per cloze value (number of observations reflected in circle size), along with the regression line and 95% confidence interval. A change in article cloze from 0 to 100 is associated with a change in amplitude of 0.296  $\mu$ V (95% confidence interval: -.08 to .67). A change in nouncloze from 0 to 100 is associated with a change in amplitude of 2.22  $\mu$ V (95% confidence interval: 1.75 to 2.69). The data for these analyses was pooled across all 9 labs.

#### 822

Figure 5. Exploratory Bayes factor analysis associated with the replication analysis, 823 824 quantifying the obtained evidence for the null hypothesis (H<sub>0</sub>) that N400 is not impacted by 825 cloze, or for the alternative hypothesis (H<sub>1</sub>) that N400 is impacted by cloze with the direction and size of effect reported by DeLong et al. Scalp maps show the common logarithm of the 826 827 replication Bayes factor for each electrode, capped at log(100) for presentation purposes. 828 Electrodes that yielded at least moderate evidence for or against the null hypothesis (Bayes 829 factor of  $\geq$  3) are marked by an asterisk. At posterior electrodes where DeLong et al. found 830 their effects, our article data yielded strong to extremely strong evidence for the null 831 hypothesis, whereas our noun data yielded extremely strong evidence for the alternative 832 hypothesis (upper graphs). These results were obtained with the procedure described in 833 DeLong et al. (no baseline correction), and with a 500 ms pre-word baseline correction

834 (lower graphs), the procedure later described by DeLong and colleagues.

835

Figure 6. Control experiment. P600 effects at electrode Pz per lab associated with flouting
of the English a/an rule. Plotted ERPs show the grand-average difference waveform and

838 standard deviation for ERPs elicited by ungrammatical expressions ('an kite') minus those

elicited by grammatical expressions ('a kite').

841 Supplementary Figure 1. Exploratory single-trial analyses: The relationship between cloze and ERP amplitude as illustrated by the mean ERP values per cloze value (number of 842 843 observations reflected in circle size), along with the regression line and 95% confidence 844 interval, from two exploratory analyses. We performed a test which used a longer baseline time windows (500 ms, left panel) to better control for pre-article voltage levels. This test 845 846 reduced the initially observed effect of article-cloze,  $\beta = .14$ , CI [-.25, .53],  $\chi^2(1) = 0.46$ , p = .50). An analysis in the 500 to 100 ms time window before article-onset (right panel) revealed 847 a non-significant effect of cloze that resembled the pattern observed after article-onset,  $\beta =$ 848 849 .16, CI [-.07, .39],  $\chi^2(1) = 1.82$ , p = .18, shedding doubt on the conclusion that the observed 850 results are due to the presentation of the articles. 851

852 **Supplementary Figure 2.** Results from exploratory Bayesian mixed-effects model analyses, represented by posterior distributions for the effect of cloze on ERP amplitudes in the N400 853 854 window. The x-axis shows cloze effect sizes (i.e., changes in microvolts associated with an 855 increase from 0% cloze probability to 100% cloze probability). The black line indicates the posterior distribution of effects; higher values of the posterior density at a given effect size 856 857 indicate higher probability that this is the true effect size in the population. The peak of the posterior distribution roughly corresponds to the point estimate of the effect size (the 858 859 regression coefficient) fitted from the Bayesian mixed effect model, i.e., the most likely value 860 of the true effect size. The middle 95% of the posterior distribution, shaded in pink, corresponds to a two-tailed 95% credible interval for the effect size—i.e., an interval that we 861 862 can be 95% confident contains the true effect. The green dotted line indicates the prior 863 distribution (i.e., our expectation about where the true effect would lie before the data were collected). For the articles, this prior is centred on  $1.25\mu$ V, an approximation of the effect 864 observed by Delong and colleagues (2005), and for the nouns it is centred on  $3.5\mu$ V. The 865 866 black connected dots illustrate the ratio between the posterior and prior distribution (i.e., the 867 Bayes Factor) at the effect size of  $0\mu V$ ; for example, a Bayes Factor of 4 suggests we can be 868 4 times more certain that the true effect is zero after having conducted this experiment than before, or, in other words, that the data increased our confidence in the null effect of zero 869 870 fourfold. We performed these analyses for each of the linear mixed-effects model analyses 871 we performed. We note that in all the article-analyses, the posterior probability of the estimated effect being greater than zero is around 80 or 90%, although this is also true for the 872 873 pre-stimulus variable, shedding doubt that the observed results are due to presentation of the 874 articles. In none of our article-analyses did zero lie outside the obtained credible interval, whereas for the nouns, zero lay outside the credible interval. These results are consistent with 875 876 a failure to replicate the size of the article-effect reported by DeLong et al. article-effect and 877 successful replication of the noun-effect.
