## SUMMARY

Numerous studies of amyloid assembly have indicated that partially folded protein species are responsible for initiating aggregation. Despite their importance, the structural and dynamic features of amyloidogenic intermediates and the molecular details of how they cause aggregation remain elusive. Here, we use  $\Delta N6$ , a truncation variant of the naturally amyloidogenic protein  $\beta_2$ -microglobulin ( $\beta_2m$ ), to determine the solution structure of a nonnative amyloidogenic intermediate at high resolution. The structure of  $\Delta N6$  reveals a major repacking of the hydrophobic core to accommodate the nonnative peptidyl-prolyl *trans*-isomer at Pro32. These structural changes, together with a concomitant pH-dependent enhancement in backbone dynamics on a microsecond-millisecond timescale, give rise to a rare conformer with increased amyloidogenic potential. We further reveal that catalytic amounts of  $\Delta N6$  are competent to convert nonamyloidogenic human wild-type  $\beta_2m$  (H $\beta_2m$ ) into a rare amyloidogenic conformation and provide structural evidence for the mechanism by which this conformational conversion occurs.

## INTRODUCTION

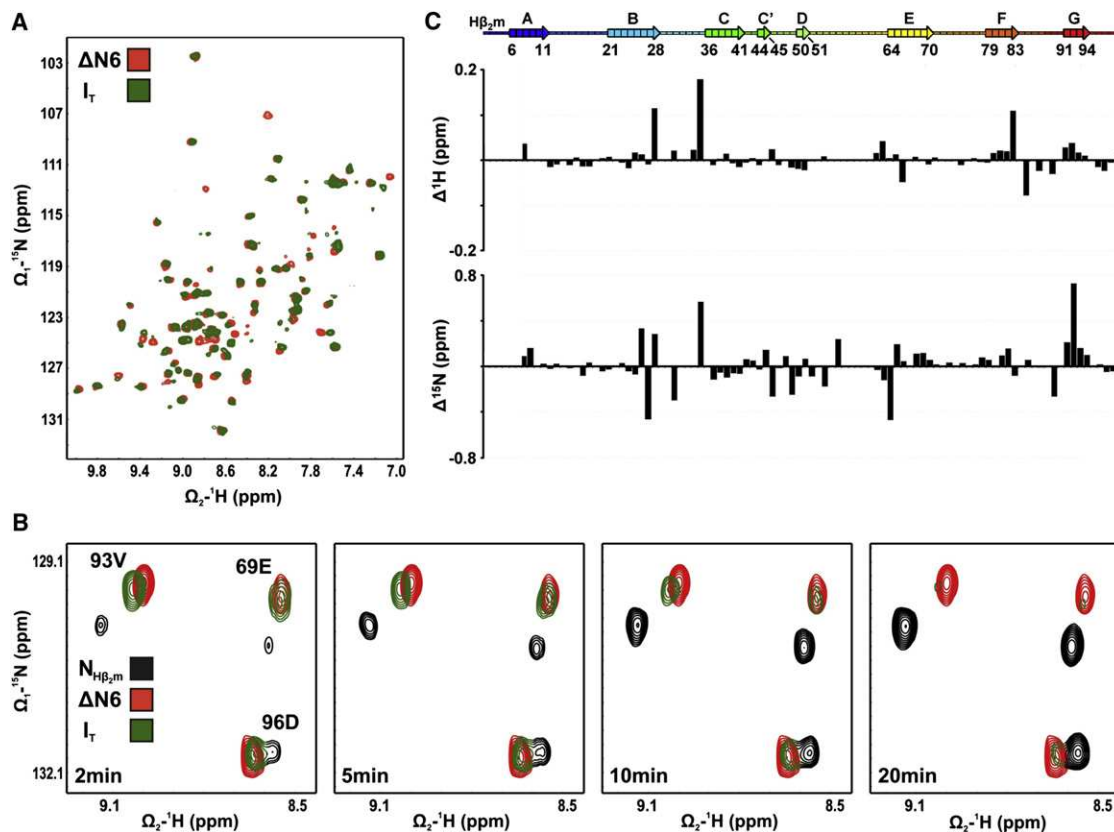

A number of human diseases involve protein misfolding events that ultimately result in the malfunctioning of the cellular machinery (Welch, 2004; Gidalevitz et al., 2006). In one class of these disorders, normally soluble proteins self-associate to form fibrillar aggregates known as amyloid (Westermarck et al., 2007). Studies have suggested that equilibration between a natively folded protein and one or more partially or more highly unfolded species is a key initiating event in amyloid formation (Booth et al., 1997; Calamai et al., 2005). In particular, for transmissible spongiform encephalopathies, the protein-only hypothesis describes the potential of infectious nonnative protein conformations (PrP<sup>Sc</sup>) to transmit their biophysical properties onto native protein conformers (PrP<sup>C</sup>), leading to the propagation of protein misfolding and aggregation (Sindi and Serio, 2009). Studies on Alzheimer's disease, Parkinson's disease, and systemic and senile amyloidosis (Kane et al., 2000; Lund-

mark et al., 2002; Rocken and Shakespeare, 2002; Xing et al., 2002; Angot and Brundin, 2009) have suggested that prion-like behavior may be a general feature of misfolded proteins (Brundin et al., 2010). However, the molecular mechanism of conformational conversion remains elusive.

Crucial to the understanding of the early stages of amyloid assembly is the elucidation of the structural changes that occur when a normally soluble protein becomes aggregation prone. Structural investigation of early aggregation-prone species is hampered, however, by their transient nature, heterogeneity, and instability (Calamai et al., 2005; Jahn and Radford, 2008). In general, the creation of unsatisfied hydrogen bond donors and acceptors, increased hydrophobic surface area, and/or loss of so-called negative design features (Richardson and Richardson, 2002) has been implicated in increasing amyloid potential (Liu et al., 2000; Monti et al., 2005; Ahn et al., 2006; Qin et al., 2007; Calabrese et al., 2008). However, the structural details of such changes and precisely how they engender amyloidogenicity remain unclear.

Here, we utilized  $\beta_2$ -microglobulin ( $\beta_2m$ ), a 99-residue protein with an immunoglobulin fold (Becker and Reeke, 1985), to investigate the initiating events of amyloid assembly in all-atom detail.  $\beta_2m$  is the major component of fibrillar deposits in patients with dialysis-related amyloidosis (DRA) (Gejyo et al., 1985). While the concentration of monomeric  $\beta_2m$  is a risk factor for amyloid deposition in DRA, the native monomer is not able to assemble into amyloid fibrils spontaneously at neutral pH in the absence of additional factors (reviewed in Calabrese and Miranker, 2009; Platt and Radford, 2009). Instead, an increase in concentration of the nonnative, amyloidogenic precursor I<sub>T</sub>, a monomeric  $\beta_2m$  conformer that contains a nonnative peptidyl-prolyl *trans*-isomer of Pro32, has been shown to be a key trigger of amyloid formation (Chiti et al., 2001; Jahn et al., 2006; Eichner and Radford, 2009). Furthermore, the presence of a *trans*-prolyl peptide bond at residue 32 (rather than *trans*-Ala32, Val32, or Gly32 [Eakin et al., 2006; Jahn et al., 2006; Sakata et al., 2008]) is required to form a species able to nucleate amyloid formation, presumably because of conformational restrictions imposed by the X-Pro32 *trans*-peptide bond itself (Eichner and Radford, 2009). The detailed structural changes occurring during interconversion between native  $\beta_2m$  and the I<sub>T</sub> state, however, remain elusive, despite a number of studies using NMR (Jahn et al., 2006; Mimmi et al., 2006; Kameda et al., 2009; Corazza et al., 2010) and X-ray crystallography (Eakin et al., 2006; Calabrese et al., 2008).

Here, we used  $\Delta N6$ , a truncation variant of human  $\beta_2m$  found in amyloid deposits of patients with DRA that lacks the N-terminal

**Figure 1.  $^1\text{H}$ - $^{15}\text{N}$  SOFAST HMQC Spectra and Chemical Shift Analysis of  $\Delta\text{N6}$  and  $\text{I}_\text{T}$**

(A) Spectra of  $\Delta\text{N6}$  (250  $\mu\text{M}$ , red) and  $\text{I}_\text{T}$  (250  $\mu\text{M}$ , green), the latter obtained approximately 2 min after refolding  $\text{H}\beta_{2\text{m}}$  from 8 M urea (pH 7.5, 25°C).

(B) Panels showing the amide resonances of Glu69, Val93, and Asp96 in  $\Delta\text{N6}$  (red), native  $\text{H}\beta_{2\text{m}}$  (black), and  $\text{I}_\text{T}$  (green), the latter obtained approximately 2 min, 5 min, 10 min, and 20 min after refolding commenced.

(C) Comparison of the chemical shifts of  $\Delta\text{N6}$  and  $\text{I}_\text{T}$  for the 76  $^1\text{H}$  or  $^{15}\text{N}$  resonances that were identified in the spectrum of both species. Note that the chemical shift differences of  $\Delta\text{N6}$  and  $\text{I}_\text{T}$  are more than one order of magnitude smaller than the chemical shift differences of  $\text{H}\beta_{2\text{m}}$  and  $\Delta\text{N6}$  (compare Figure 1C with Figures 2B and 2D). Missing  $^1\text{H}$ - $^{15}\text{N}$  resonances in the spectrum of  $\text{I}_\text{T}$  (1–7, 29, 30, 33, 53, 55–61, 86, and 88) are either broadened due to intermediate exchange processes or degenerate with other residues. The rainbow ribbons and numbers above indicate  $\beta$  strands in  $\text{H}\beta_{2\text{m}}$  calculated from the final set of 30 lowest-energy structures (PDB code 2XKS) using DSSPcont (Carter et al., 2003). All samples contained 0.8 M urea.

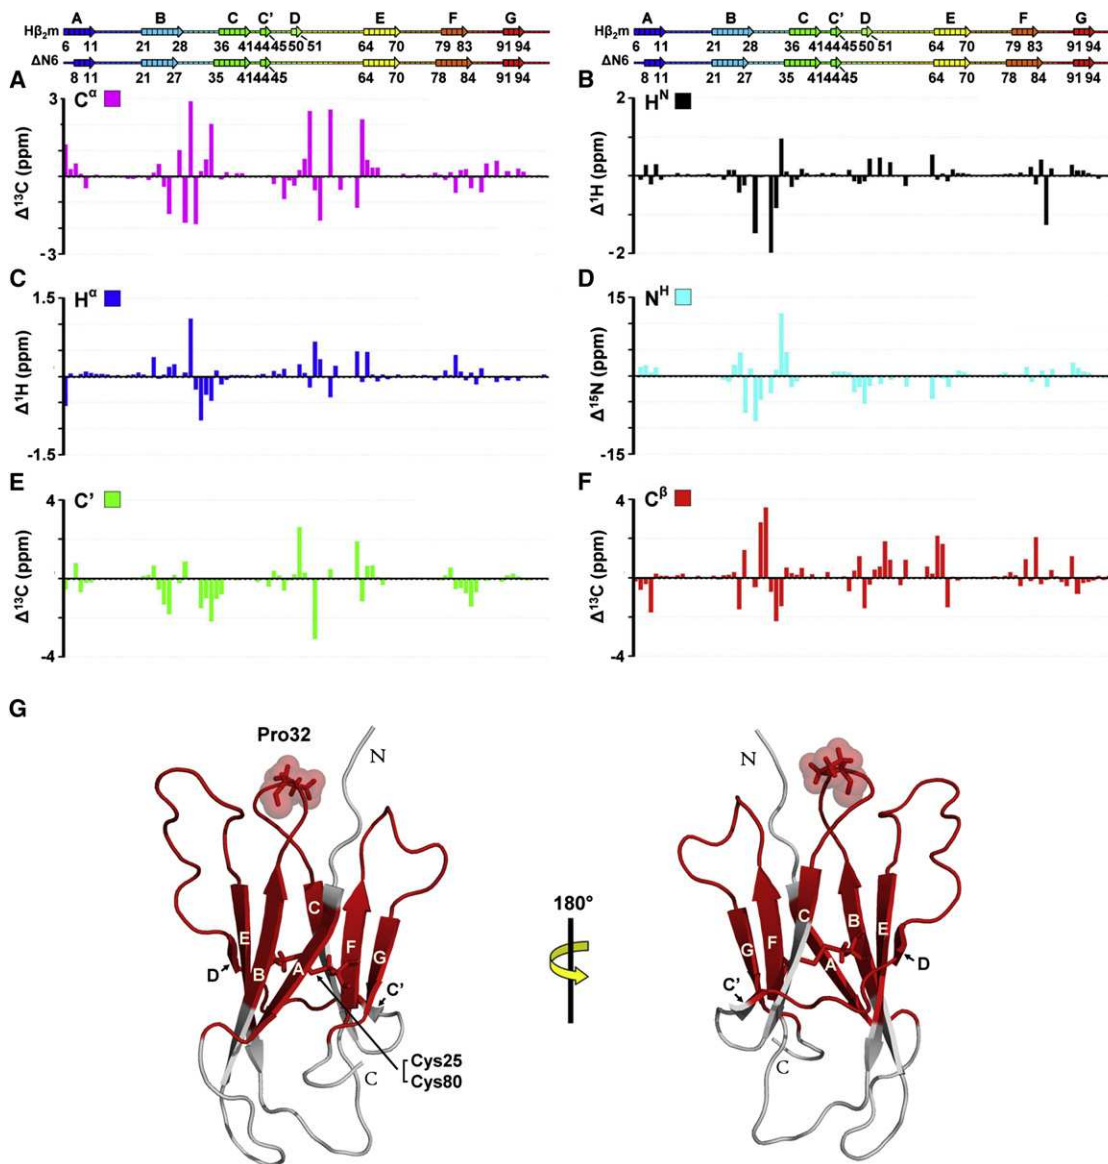

six amino acids and closely mimics  $\text{I}_\text{T}$  (Eichner and Radford, 2009), to determine the solution structure of this nonnative, amyloidogenic intermediate at high resolution using NMR spectroscopy. The results reveal a remarkable repacking of the hydrophobic core that is reminiscent of, but distinct from, the nonamyloidogenic  $\text{Cu}^{2+}$ -bound hexameric state previously captured by crystallography (Calabrese et al., 2008). Most strikingly, we show that  $\Delta\text{N6}$  is able to interact specifically with human wild-type  $\beta_{2\text{m}}$  ( $\text{H}\beta_{2\text{m}}$ ), causing it to adopt an amyloid-competent structure and thereby reveal the mechanism of conformational conversion of a naturally occurring amyloidogenic protein in atomistic detail.

## RESULTS

### Real-Time NMR Studies Confirm the Structural Resemblance of $\Delta\text{N6}$ and $\text{I}_\text{T}$

To confirm the structural similarity of  $\Delta\text{N6}$  with the slow-folding intermediate,  $\text{I}_\text{T}$ , that is known to be highly amyloidogenic (Chiti

et al., 2001; Jahn et al., 2006; Eichner and Radford, 2009),  $\text{H}\beta_{2\text{m}}$  was denatured in 8 M urea and then refolded by 10-fold dilution into buffer at pH 7.5, 25°C. SOFAST  $^1\text{H}$ - $^{15}\text{N}$  heteronuclear multiple-quantum coherence (HMQC) spectra (Schanda and Brutscher, 2005) were then acquired approximately 2 min after refolding commenced, at which time  $\text{I}_\text{T}$  is populated to about 75% (Eichner and Radford, 2009) (Figure 1A). The spectrum reveals 76 cross-peaks corresponding to the  $\text{I}_\text{T}$  state, 68 of which overlay with resonances of  $\Delta\text{N6}$  ( $^1\text{H}/^{15}\text{N}$  within  $\pm 0.04/0.2$  ppm, respectively). Figure 1B shows one region of the SOFAST  $^1\text{H}$ - $^{15}\text{N}$  HMQC spectra obtained at different folding times. The data show that resonances arising from the kinetically formed  $\text{I}_\text{T}$  superpose with those of  $\Delta\text{N6}$  at equilibrium. The peaks corresponding to  $\text{I}_\text{T}$  then decrease in intensity with increased folding time, as resonances of the native state emerge. Resonances in the spectrum of  $\Delta\text{N6}$  were assigned using standard procedures (see below). Figure 1C shows the difference in chemical shift of the 76 cross-peaks identified for  $\text{I}_\text{T}$  by comparison with the assigned spectrum of  $\Delta\text{N6}$ . The data reveal

**Figure 2. Chemical Shift Analysis of Native Hβ<sub>2</sub>m and ΔN6**

(A–F) Differences in chemical shift of C<sup>α</sup> (A), H<sup>N</sup> (B), H<sup>α</sup> (C), N<sup>H</sup> (D), C<sup>β</sup> (E), and C<sup>β</sup> (F) between native Hβ<sub>2</sub>m and ΔN6 (pH 7.5, 25°C). Rainbow-colored ribbons and numbers above indicate the secondary structure contents of Hβ<sub>2</sub>m and ΔN6.

(G) Lowest-energy structure of Hβ<sub>2</sub>m (PDB code 2XKS) showing the eight native β strands: A (6–11), B (21–28), C (36–41), C' (44–45), D (50–51), E (64–70), F (79–83), and G (91–94). Residues colored in red differ significantly ( $\Delta^1\text{H}/^{15}\text{N}/^{13}\text{C} > 0.2/0.8/0.4$  ppm) in chemical shift between Hβ<sub>2</sub>m and ΔN6. Pro32 (stick, spheres) is highlighted (see also Figure S1 and Table S1).

differences in chemical shift of  $<0.2$  ppm (<sup>1</sup>H) or 0.8 ppm (<sup>15</sup>N), confirming the fidelity of ΔN6 as a structural mimic of I<sub>T</sub>.

### The Structure of ΔN6

To allow detailed comparison of the structure and dynamics of ΔN6 and native Hβ<sub>2</sub>m, chemical shift assignment of the spectra of both proteins was carried out (Figure S1). <sup>1</sup>H-<sup>15</sup>N assignments were obtained for 88 out of 99 residues of Hβ<sub>2</sub>m and 84 out of 93 residues of ΔN6. <sup>1</sup>H-<sup>13</sup>C side-chain assignments were obtained for 95% of residues in Hβ<sub>2</sub>m and 90% of residues for ΔN6. The

results indicate, as anticipated, that the X-Pro32 peptide bond adopts a *trans*-conformation in ΔN6 (Table S1). Moreover, comparison of the chemical shift differences between Hβ<sub>2</sub>m and ΔN6 (Figures 2A–2F) revealed that of the 93 residues in ΔN6, approximately 60 residues (i.e., more than half of the molecule) (Figure 2G) have chemical shifts that deviate substantially ( $\Delta^1\text{H}/^{15}\text{N}/^{13}\text{C} > 0.2/0.8/0.4$  ppm for all resonances analyzed) from the values for native Hβ<sub>2</sub>m. While many of these residues lie in spatial proximity to Pro32 in native Hβ<sub>2</sub>m (Trinh et al., 2002), some are distant to this site, consistent with Pro32 being

\* Pairwise rmsds were calculated over ordered regions from an ensemble of 30 structures superimposing the restrained residues in native H $\beta_2$ m (3–28, 30–31, 34–45, 48–53, 55–57, 63–86, 89–98) and  $\Delta$ N6 (7–28, 31–52, 64–86, 89–98).

the epicenter of widespread conformational changes in  $\Delta$ N6 (Figure 2G).

To determine the structures of native H $\beta_2$ m and  $\Delta$ N6, 2065 or 2565 nuclear Overhauser enhancements (nOe) (Tables 1 and S2), 128 or 118 dihedral angles, and 75 or 76 residual dipolar couplings (RDC) were obtained for each protein, respectively (Table 1). Structural ensembles were then calculated using the PASD algorithm (Kuszewski et al., 2004) to obtain 50 preliminary structures that were transferred into ARIA 2.0 (Rieping et al., 2007) for further refinement (see Supplemental Experimental

**Figure 3. Solution Structures of Native H $\beta_2$ m and  $\Delta$ N6**

(A) Cartoon representation of five lowest-energy structures of native H $\beta_2$ m and  $\Delta$ N6 with  $\beta$  strands highlighted in rainbow colors. The cartoon overlay shows the lowest-energy structures of native H $\beta_2$ m (black) and  $\Delta$ N6 (red). Pro32 (sticks, spheres) and the disulfide bond (Cys25-Cys80, sticks) are highlighted. (B) Bar chart showing the C $\alpha$  rms (Å) of the overlay shown in (A). The rainbow-colored arrows above indicate residues involved in  $\beta$  strand structure of H $\beta_2$ m and  $\Delta$ N6.

(C) Overlay of lowest-energy structures of native H $\beta_2$ m (black) and  $\Delta$ N6 (red). Residues Pro32, Phe30, Phe62, His84, Leu64, Ile35, Phe70, and Trp95 and the disulfide bond (Cys25-Cys80, sticks) are highlighted. Structures were drawn using PyMOL (DeLano, 2002) (see also Figure S2 and Table S2).

Procedures). In the final ensemble of 30 structures (Figure 3A), the rmsd of backbone atoms ( $^1H$ ,  $^{15}N$ ,  $^{13}C\alpha$ ,  $^{13}C'$ ) within ordered regions is 0.42 and 0.28 Å from the mean structures of native H $\beta_2$ m and  $\Delta$ N6, respectively. The structural ensembles reveal that  $\Delta$ N6 retains a native-like  $\beta$  sandwich fold containing two antiparallel  $\beta$  sheets tethered by a single disulfide bridge between Cys25 and Cys80 (Figure 3A). Minor differences are observed in the lengths of  $\beta$  strands, including the short D strand that adopts variable structures in  $\Delta$ N6 (see Supplemental Experimental Procedures). Despite being highly amyloidogenic,

therefore,  $\Delta N6$  contains a well-defined structure under the conditions employed that, in terms of the main chain, is not significantly perturbed compared with native  $H\beta_2m$  (within ordered regions, the  $C\alpha$  rms between  $H\beta_2m$  and  $\Delta N6$  is approximately 1.3 Å) (Figure 3B).

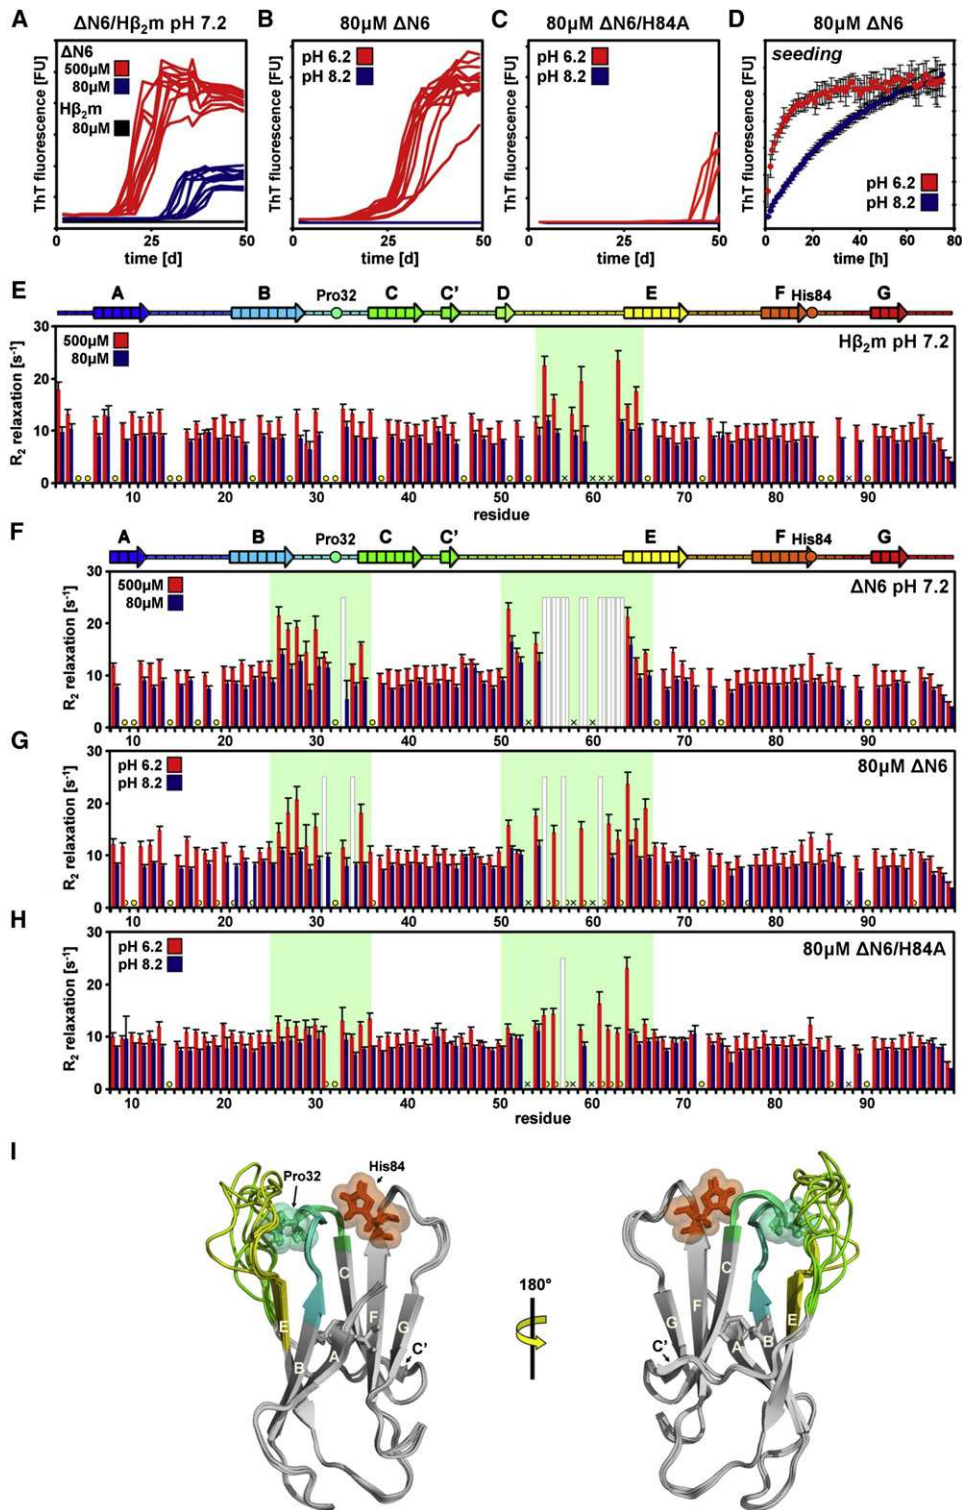

In contrast with the minor differences in the main chain of  $H\beta_2m$  and  $\Delta N6$ , dramatic differences are observed for side chains, both close to Pro32 and distal to this site, that result from a substantial repacking of the molecule's core (Figure 3C). Of the 21 residues that comprise the hydrophobic core of native  $H\beta_2m$ , 17 undergo significant movement ( $>2$  Å) between the two structures (Tables 1 and S2). Most strikingly, the aromatic side chain of Phe30 moves out of the hydrophobic core in  $\Delta N6$  toward the surface where the N terminus was originally placed (Figure 3C). This large movement ( $H\zeta$  of Phe30 moves by  $\sim 9.5$  Å) is accompanied by further restructuring of side chains in the core (Figure 3C). In particular, the X-Pro32 *cis*-peptide bond is relaxed toward the more favored *trans*-peptidyl-prolyl isomer ( $H\gamma$  moves by  $\sim 9.6$  Å). As a consequence, the backbone ( $^1H$ ,  $^{15}N$ ,  $^{13}C$ ) interactions between Phe30 and Phe62 are disrupted so that the side chain of the latter rotates by  $>90^\circ$  around  $C\gamma$  and loses connection with the BC-loop ( $C\gamma$  moves by  $\sim 7.4$  Å) (Figure 3C). The change in rotameric state of Phe30 also disrupts the main-chain hydrogen bonding between Ser28 and Lys6/Met6 in the A and B strands, leading to a loss in  $\beta$  strand structure at these residues and causing the side chain of His84 to rotate around its  $C\gamma$  by  $\sim 45^\circ$  (Figure 3C). The cavity left by Phe30 is mostly filled by the hydrophobic side chains of Pro32, Leu64, and Ile35, the latter two side chains changing their rotamer angles so as to accomplish this. The conformational changes that result from isomerization of the X-Pro32 peptide bond do not stop at Cys25–Cys80 disulfide, but propagate deep into the other half of the molecule, leading to movements of the side chains of Asn21, Phe70, Phe78, and Trp95 (Figure 3C). These side-chain movements result in differences in surface charge and hydrophobicity (Figure S2A), consistent with previous suggestions that the N terminus of  $H\beta_2m$  is important in maintaining the native hydrophobic folding balance (Esposito et al., 2000). The data thus show that docking of the N-terminal hexapeptide during the last steps in folding locks  $H\beta_2m$  into a thermodynamically stable native structure that contains an unfavorable X-Pro32 *cis*-peptide bond. Consistent with this, resonances arising from the N-terminal seven residues were not identified in the HMQC spectrum of  $I_T$  (Figure 1A), suggesting that this region is displaced from its native conformation in the folding intermediate. Once the N-terminal hexapeptide is displaced, or removed as in  $\Delta N6$ , the molecule relaxes toward an amyloidogenic conformation containing the X-Pro32 *trans*-isomer.

### The Dynamics of $\Delta N6$ Reveal a Rarely Populated Nucleation- and Elongation-Competent Species

$\Delta N6$  has been shown to be highly aggregation prone compared with  $H\beta_2m$ , suggesting that this variant is uniquely able to sample one or more amyloidogenic conformers at physiological pH (Esposito et al., 2000; Eichner and Radford, 2009). Accordingly, amyloid fibrils are obtained after incubation of  $\Delta N6$  at  $37^\circ C$ , pH 7.2 in a protein-concentration-dependent manner

(Figure 4A). While  $\Delta N6$  converts quantitatively into insoluble aggregates, as indicated by a lack of residual monomer in the supernatant after fibrillation is complete, as judged by SDS-PAGE (see Experimental Procedures) (data not shown), native  $H\beta_2m$  does not show an increase in ThT fluorescence and remains soluble (judged by SDS-PAGE, data not shown) even after 50 days incubation (Figure 4A). Further experiments revealed that the amyloidogenicity of  $\Delta N6$  is highly pH dependent: no fibrils result when the protein (80  $\mu M$ ) is incubated at pH 8.2 for 50 days, while the protein converts into amyloid fibrils at pH 6.2 more rapidly ( $t_{lag} = 15 \pm 4$  days) than at pH 7.2 ( $t_{lag} = 35 \pm 4$  days) at this protein concentration (compare Figures 4A and 4B). Replacing His84 (a residue in close proximity to Pro32) (Figure 3C) with alanine in  $\Delta N6$  substantially reduces the ability of this protein to assemble *de novo* into amyloid fibrils (Figure 4C). The rate of elongation of fibrillar seeds of  $\Delta N6$  by  $\Delta N6$  monomers is also enhanced at pH 6.2 compared with pH 8.2 (Figure 4D). The data indicate, therefore, that protonation of His84 and possibly other side chains with  $pK_a \sim 7$  amplifies the amyloidogenicity of  $\Delta N6$ , presumably by causing conformational changes that increase the population of species with enhanced amyloid potential within the ensemble of structures available.

To explore in more detail the enhanced ability of  $\Delta N6$  to nucleate amyloid formation compared with  $H\beta_2m$ , the dynamic properties of the two proteins were compared. Whereas  $^{15}N$   $R_1$  and  $\{^1H\}^{15}N$  nOe relaxation measurements show limited motions on a picosecond-to-nanosecond timescale for both proteins (Figure S2B), significantly higher  $^{15}N$   $R_2$  relaxation rates were observed for residues 25–34 (BC-loop) in  $\Delta N6$  compared with  $H\beta_2m$  (Figures 4E and 4F). Additionally, several residues in the DE-loop (54–57, 59, 61–63) of  $\Delta N6$  relax too rapidly ( $R_2 \geq 25$  s $^{-1}$ , indicated by gray bars in Figures 4F–4H) to determine their  $R_2$  rates reliably but were readily quantified for  $H\beta_2m$ , suggestive of enhanced chemical exchange processes on a microsecond-to-millisecond timescale for these residues in the former protein (Figures 4E and 4F). The local dynamics of residues 25–34 (BC-loop) and 51–66 (DE-loop) of  $\Delta N6$  are dependent on pH, with complete suppression of their enhanced dynamics at pH 8.2 and significant enhancement relative to other residues at pH 6.2 (Figure 4G), consistent with the pH dependency of fibril formation. Finally, the pH-dependent increase in  $R_2$  dynamics of residues 25–34 in  $\Delta N6/H84A$  is substantially reduced at pH 6.2 compared with  $\Delta N6$  (Figures 4G and 4H), consistent with the view that protonation of His84 plays a role in enhancing the dynamics of the BC-loop (Figure 4I) and the amyloidogenicity of  $\Delta N6$ . Analysis of  $^1H$ - $^{15}N$  HSQC spectra of  $\Delta N6$  at increased protein concentration revealed a set of resonances (in the BC- and DE-loops) that shifted significantly dependent on the protein concentration, suggesting that fibril formation of  $\Delta N6$  occurs by transient oligomerization via a newly formed dimerization interface involving these residues (Figures S3A and S3B). Importantly, a clear correlation is observed between chemical shift alterations of  $\Delta N6$  with pH and protein concentration (data not shown). These data suggest that protonation events and protein conformational changes are coupled processes that together initiate the aggregation cascade.

**Figure 4. Amyloid Formation and Protein Dynamics of Native  $H\beta_2m$  and  $\Delta N6$**

(A) De novo fibril formation of 500  $\mu M$   $\Delta N6$  (red), 80  $\mu M$   $\Delta N6$  (blue), or 80  $\mu M$  native  $H\beta_2m$  (black) at pH 7.2, 37°C, 200 rpm.

(B and C) De novo fibril assembly of 80  $\mu M$   $\Delta N6$  or  $\Delta N6/H84A$  at pH 6.2 (red) or pH 8.2 (blue).

(D) Seeded fibril assembly of 80  $\mu M$   $\Delta N6$  at pH 6.2 (red) or pH 8.2 (blue) using 10% (w/w)  $\Delta N6$  fibrillar seeds. The error bars are the standard deviation of six replicates. The presence of fibrillar material for all samples was confirmed by negative-stain electron microscopy (EM) (not shown).

### **$\Delta$ N6 Converts Native H $\beta_2$ m into an Amyloid-Competent State**

Given the inherent potential of  $\Delta$ N6 to nucleate fibril formation *in vitro*, we speculated that bimolecular collision between  $\Delta$ N6 and H $\beta_2$ m might enhance the amyloid potential of the latter protein by its conversion to an amyloidogenic state, akin to conformational conversion in prions. To test this hypothesis, H $\beta_2$ m and  $\Delta$ N6 were incubated separately or as mixtures at a final total concentration of 80  $\mu$ M in ratios of 1:1, 1:9, or 1:99 ( $\Delta$ N6:H $\beta_2$ m) at pH 7.2, 37°C while shaking at 200 rpm (Figure 5 and data not shown). Whereas H $\beta_2$ m incubated alone does not form fibrils in the time frame of the experiment (100 days) (Figure 5A), consistent with previous results (Eichner and Radford, 2009), 50% (1:1), 10% (1:9), or even 1% (1:99) of  $\Delta$ N6 is capable of catalyzing assembly of H $\beta_2$ m into amyloid-like fibrils with lag times of  $\sim 30 \pm 3$ ,  $\sim 40 \pm 8$ , and  $\sim 75 \pm 8$  days, respectively (Figures 5B and 5C and data not shown). Crucially, these lag times are shorter than those obtained when the same concentration of  $\Delta$ N6 is incubated alone ( $\sim 40 \pm 5$  days,  $\sim 50 \pm 7$  days, and  $>100$  days [Figures 5B and 5C and data not shown]), indicating that productive interactions between  $\Delta$ N6 and H $\beta_2$ m catalyze assembly of the latter into amyloid fibrils. As a control experiment, wild-type murine  $\beta_2$ m (M $\beta_2$ m) was incubated alone or was mixed to a total protein concentration of 80  $\mu$ M with different concentrations of  $\Delta$ N6 (50% [1:1], 10% [1:9], and 1% [1:99]) (Figures 5A–5C). M $\beta_2$ m is 70% identical in sequence to H $\beta_2$ m but has been shown to be unable to assemble into amyloid fibrils at acidic pH (Ivanova et al., 2004). No fibrils were observed when M $\beta_2$ m was incubated alone at pH 7.2, 37°C for 100 days (Figure 5A). Remarkably, the presence of stoichiometric concentrations of M $\beta_2$ m abolishes the ability of  $\Delta$ N6 to form amyloid fibrils (Figure 5B), and catalytic amounts (1%) of  $\Delta$ N6 are not able to enhance amyloid formation from M $\beta_2$ m (Figure 5C). To confirm these findings, the amount of soluble material remaining in each sample was quantified using SDS-PAGE and fibril formation was monitored using EM (Figures 5A–5C). While all protein in 1:1 mixtures of  $\Delta$ N6 and M $\beta_2$ m remained soluble (Figure 5B), 100%,  $\sim 50\%$ , and  $\sim 10\%$  conversion of H $\beta_2$ m into insoluble amyloid aggregates occurred when the protein was incubated with 50% (1:1), 10% (1:9), or 1% (1:99)  $\Delta$ N6 ( $\Delta$ N6:H $\beta_2$ m), respectively, consistent with the increased ThT fluorescence and the presence of fibrillar material in EM images of these samples (Figures 5B and 5C). The results indicate, therefore, that  $\Delta$ N6 is able to convert H $\beta_2$ m into a conformer capable of forming amyloid fibrils even when added in catalytic amounts. Bimolecular collision of  $\Delta$ N6 with the highly

homologous M $\beta_2$ m protein, by contrast, abolishes the aggregation potential of the truncated protein.

### **Atomistic Description of Conformational Conversion by Bimolecular Collision of $\Delta$ N6 and H $\beta_2$ m**

To probe the molecular mechanism of conformational conversion of H $\beta_2$ m to an amyloidogenic state, backbone dynamics of  $^{15}$ N-H $\beta_2$ m in the absence or presence of  $^{14}$ N- $\Delta$ N6 (Figure 6A) were assessed using  $^{15}$ N NMR  $R_2$  measurements at pH 6.2, 37°C. These experiments revealed that adding  $^{14}$ N- $\Delta$ N6 to  $^{15}$ N-H $\beta_2$ m increases the  $^{15}$ N relaxation rates of residues 13–22 in the AB-loop of H $\beta_2$ m substantially (Figures 6A and 6C) in a pH-dependent manner (Figure S4A). Addition of equivalent concentrations of  $^{14}$ N-H $\beta_2$ m or  $^{14}$ N-M $\beta_2$ m has no effect on the  $R_2$  relaxation rates of  $^{15}$ N-H $\beta_2$ m (Figure 6B), indicating that the interaction of  $\Delta$ N6 with H $\beta_2$ m is specifically able to alter the dynamics of the latter protein. Note that the enhanced  $R_2$  relaxation rates of residues in the AB-loop of H $\beta_2$ m in the presence of  $\Delta$ N6 are not accompanied by  $^1$ H- $^{15}$ N chemical shift alterations (Figure S4B), implying that the concentration of the encounter complex between H $\beta_2$ m and  $\Delta$ N6 is low ( $<5\%$ ) and its formation occurs on an intermediate NMR timescale ( $\sim$ milliseconds).

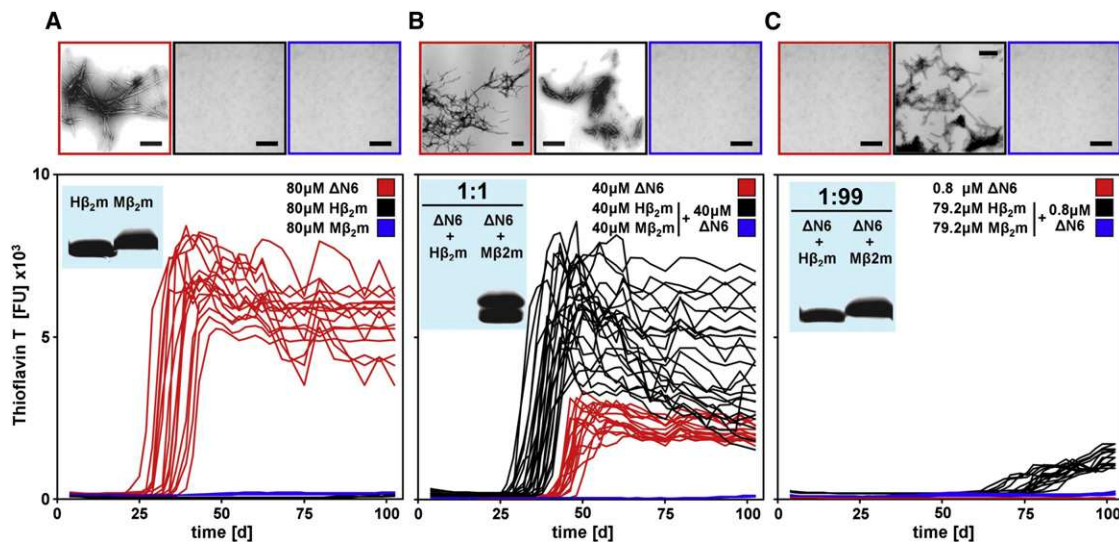

The AB-loop (residues 13–22) (Figure 6C) has been shown to adopt different conformations in different crystal structures of H $\beta_2$ m, dependent on the contacts made in the crystal lattice (Ricagno et al., 2009). Additionally, it has been proposed that Pro14, which introduces rigidity into the AB-loop (Figure 6C), may play a role in triggering a conformational switch wherein the A strand is displaced toward a more open protein conformation (Rosano et al., 2004). As shown above, such a conformational transition would favor relaxation of the X-Pro32 *cis*-peptide bond to the *trans*-isomer by providing the conformational freedom required for the structural changes linked to this isomerization event to occur. To determine whether the increased dynamics of the AB-loop of H $\beta_2$ m induced by the presence of  $\Delta$ N6 is linked to displacement of the A-strand, the hydrogen exchange (HX) rates of individual residues of  $^{15}$ N-H $\beta_2$ m, alone or mixed with a molar equivalent of  $^{14}$ N- $\Delta$ N6, were determined at pH 6.2, 37°C (Figure 6D). The results revealed a 2- to 3-fold increase in the HX rates of residues in the N-terminal region of H $\beta_2$ m in the presence of  $^{14}$ N- $\Delta$ N6 (exemplified by Tyr10, Asn24, Tyr26, and Ser28 in Figure 6D) compared to H $\beta_2$ m alone. By contrast, little effect ( $<1.5$ -fold) was observed for other residues in the protein (exemplified by Leu64 and Lys91 in Figure 6D). The data thus show that bimolecular collision of  $\Delta$ N6 with H $\beta_2$ m increases the

(E and F)  $^{15}$ N transverse relaxation measurements ( $R_2 = 1/T_2$ ) of 500  $\mu$ M (red) or 80  $\mu$ M (blue) native H $\beta_2$ m or  $\Delta$ N6 at pH 7.2, 25°C. Rainbow-colored ribbons above indicate the secondary structure content of native H $\beta_2$ m and  $\Delta$ N6.

(G and H)  $^{15}$ N transverse relaxation measurements of 80  $\mu$ M  $\Delta$ N6 or  $\Delta$ N6/H84A at pH 6.2 or pH 8.2 (red and blue, respectively) at 25°C. Grey bars indicate a lower limit of the  $R_2$  for residues too weak to determine the value more precisely ( $>25$  s $^{-1}$ ). Circles highlight residues for which  $R_2$  could not be determined due to resonance overlap, line broadening, or the residue being a proline. Black crosses mark missing assignments. Green boxes highlight residues that show significant differences in local backbone dynamics in the different samples. The error (E–H) was estimated using duplicates.

(I) Cartoon representation of five lowest-energy structures of  $\Delta$ N6, highlighting Pro32 and His84 (sticks, spheres) and the regions that show enhanced local dynamics (residues 26–35 [dark green] and 51–66 [light green–yellow]) in the different samples. Note that both H $\beta_2$ m and  $\Delta$ N6 show a uniform increase in  $R_2$  rates at higher protein concentrations, which are distinct from the pH-dependent enhanced  $R_2$  rates measured for residues in spatial proximity to Pro32 in  $\Delta$ N6. The global increase in  $R_2$  rates observed for all residues in H $\beta_2$ m and  $\Delta$ N6 at increased protein concentration most likely indicates transient oligomerization not associated with amyloid formation (see also Figure S3).

(B) ThT fluorescence of 40  $\mu$ M  $\Delta$ N6 incubated alone (red) or as mixtures of 40  $\mu$ M H $\beta_2$ m and 40  $\mu$ M  $\Delta$ N6 (black) or 40  $\mu$ M M $\beta_2$ m and 40  $\mu$ M  $\Delta$ N6 (blue).

(C) ThT fluorescence of 0.8  $\mu$ M  $\Delta$ N6 (red) or mixtures of 79.2  $\mu$ M H $\beta_2$ m and 0.8  $\mu$ M  $\Delta$ N6 (black) or 79.2  $\mu$ M M $\beta_2$ m and 0.8  $\mu$ M  $\Delta$ N6 (blue). The upper panels show negative-stain EM images of the samples, using the same color coding. Scale bar = 100 nm. The insets (A–C) show SDS-PAGE analysis of the soluble fraction obtained after centrifugation (14,000  $\times$  g, 10 min) of the samples (see also Figure S5).

conformational dynamics of the N-terminal region of the protein, which permits the isomerization of the X-Pro32 bond and switches on the pathway toward the amyloid state.

## DISCUSSION

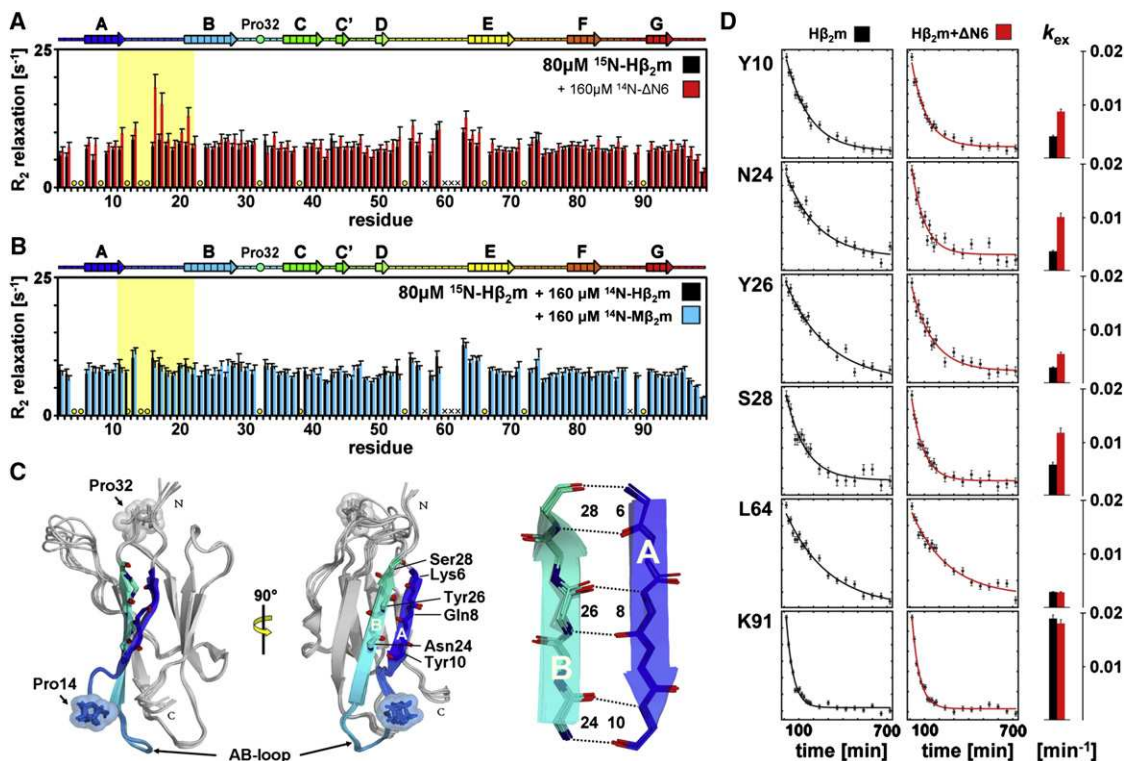

### Role of the N Terminus in the Folding and Stabilization of H $\beta_2$ m

A key question in understanding amyloidosis is the nature of the early conformational changes that tip the equilibrium from correct folding toward the population of amyloidogenic species. Furthermore, how bimolecular collisions between a native protein and a misfolded or nonnative state enable conversion of an initially innocuous protein into an amyloidogenic conformation remains poorly understood at a molecular level. Here, we have used  $\Delta$ N6 to investigate these phenomena. The solution structure of  $\Delta$ N6 shows that this amyloidogenic protein retains a native-like structure, revealing that structural considerations alone cannot explain the enhanced amyloidogenic potential of this variant. Examination of the solution structures of native H $\beta_2$ m and  $\Delta$ N6, nonetheless, reveals significant side-chain rearrangements comprising more than half of the protein's core that occur when the X-Pro32 peptide bond isomerizes to its *trans*-state, some of which involve residues shown hitherto to undergo structural changes in conformers of  $\beta_2$ m trapped in protein crystals (Eakin et al., 2006; Calabrese et al., 2008). Despite the structural similarities of  $\Delta$ N6 in solution and Cu<sup>2+</sup>-bound  $\beta_2$ m observed crystallographically (Figures S2C–S2E), only  $\Delta$ N6 is able to form amyloid fibrils efficiently in vitro (Eichner and Radford, 2009), suggesting that differences in structure and/or dynamics of these species are critical in endowing the potential to form amyloid.

While  $\Delta$ N6 retains a native topology and is only marginally destabilized compared with H $\beta_2$ m ( $\Delta\Delta G_{UN}^\circ = 3.8$  kJ mol<sup>-1</sup>) (Eichner and Radford, 2009), removal of the N-terminal six residues disrupts the kinetic stability of the protein, such that it is no longer strongly protected from HX (Figure S3C) and interconverts rapidly with other conformers on a microsecond-to-millisecond timescale, as revealed by its enhanced  $R_2$  values compared with H $\beta_2$ m (Figures 4E and 4F). Furthermore, the absence of well-resolved resonances for residues 1–7 in  $I_T$  (Figure 1A) suggests that these residues are not natively attached to the protein in this folding intermediate. The N-terminal residues of  $\beta_2$ m (Figure 7A, shown in blue) thus act as a postassembly clamp, side chains in this region stabilizing residues in the BC-loop and its main chain forming hydrogen bonds to the adjacent native  $\beta$  strand B. These interactions lock the X-Pro32 peptide bond in the *cis*-isomer, preventing its isomerization to the relaxed *trans*-form and the consequent release of the side chain of Phe30 from the hydrophobic core that, together, initiate a cascade of events that opens up the pathway toward aggregation. Proline-mediated loop dynamics associated with protein assembly have been observed in a number of protein systems in vitro and in vivo, suggesting that proline-mediated triggering of amyloidosis is not unique to  $\beta_2$ m. For example, a misfolded conformer of human immunoglobulin light chain (O'Nuallain et al., 2007), an amyloid intermediate of stefin B (Jenko Kokalj et al., 2007), and the cell-cycle protein p13suc1 (Rousseau et al., 2001) have all been shown to possess aggregation mechanisms dependent on isomerization of X-Pro bonds.

### $\Delta$ N6: An In Vivo Culprit of DRA

Despite the fact that  $\beta_2$ m is among the most extensively studied proteins involved in human amyloid disease (Platt and Radford,

**Figure 6. Atomistic Details of Specific Interactions between Native H $\beta_2$ m and  $\Delta$ N6**

(A and B)  $^{15}\text{N}$  transverse relaxation measurements ( $R_2 = 1/T_2$ ) of  $80\ \mu\text{M}$   $^{15}\text{N}$ -H $\beta_2$ m in the absence (black) or presence (red) of  $160\ \mu\text{M}$   $^{14}\text{N}$ - $\Delta$ N6 at pH 6.2,  $37^\circ\text{C}$ , and  $80\ \mu\text{M}$   $^{15}\text{N}$ -H $\beta_2$ m in the presence of  $160\ \mu\text{M}$   $^{14}\text{N}$ -H $\beta_2$ m (black) or  $^{14}\text{N}$ -M $\beta_2$ m (blue) under the same conditions. Circles highlight residues for which data could not be obtained due to resonance overlap, line broadening, or the residue being proline. Black crosses mark missing assignments. Light yellow boxes emphasize residues 11–21 (AB-loop) that show increased backbone dynamics upon  $\Delta$ N6 binding. The error was estimated using duplicates.

(C) Five lowest-energy structures of native H $\beta_2$ m: Pro32 (light gray) and Pro14 (blue) are highlighted in sticks and spheres; the  $\beta$  strands A and B and the AB-loop are rainbow colored from blue to cyan. Residues that establish essential hydrogen bonds between  $\beta$  strands A and B (Lys6–Ser28, Gln8–Tyr26, Tyr10–Asn24) are highlighted in line representation alongside.

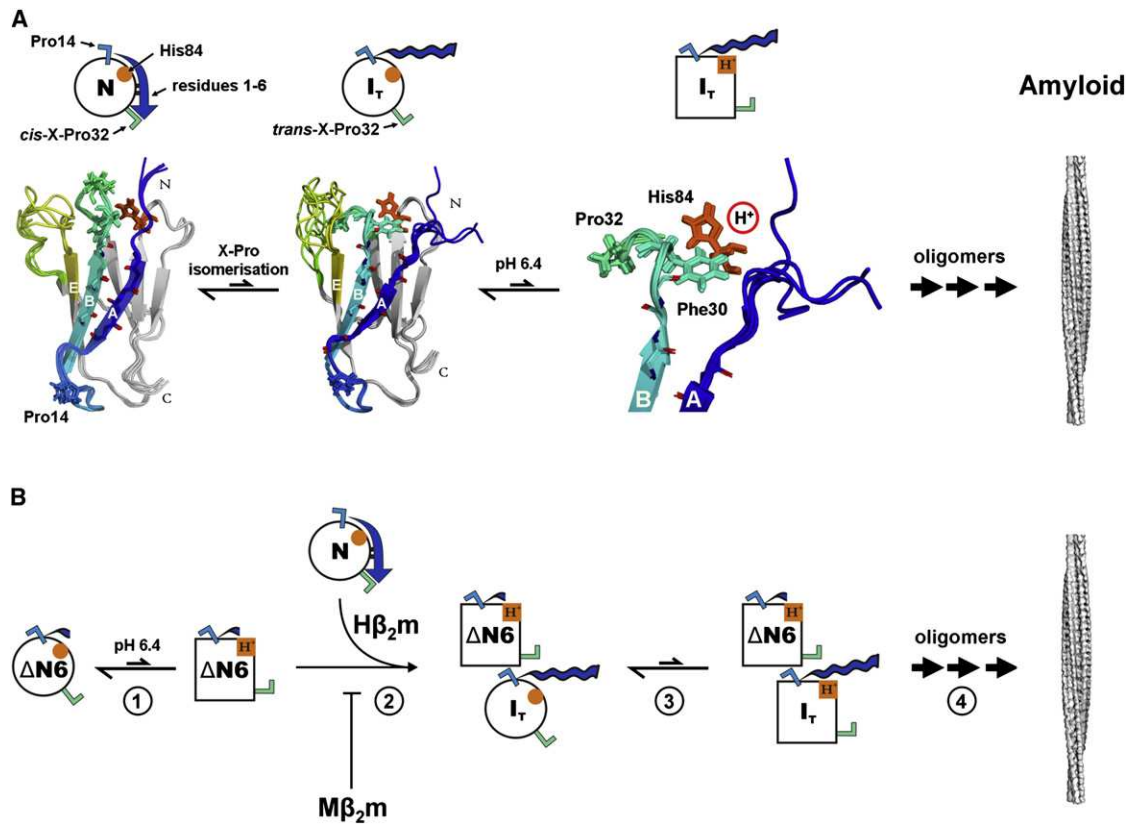

(D) H–D exchange rates of  $80\ \mu\text{M}$   $^{15}\text{N}$ -H $\beta_2$ m alone (black) or in the presence of  $160\ \mu\text{M}$   $^{14}\text{N}$ - $\Delta$ N6 (red) at pH 6.2,  $37^\circ\text{C}$ . The black or red line is a single exponential fit of the data obtained. The error was estimated from the noise level of the experiment. The bars alongside depict the H–D exchange rate constant ( $k_{\text{ex}}$ ) of each residue, colored in the same manner (see also Figure S4).

2009), the initiating factors in DRA remain unclear. Many scenarios have been suggested, including partial unfolding of  $\beta_2$ m on the collagen surface, mild acidification in arthritic joints, stabilization of rare fibrils that may form from H $\beta_2$ m by glycosaminoglycans (Esposito et al., 2000; Yamamoto et al., 2004b; Eakin and Miranker, 2005; Mimmi et al., 2006; Myers et al., 2006; Relini et al., 2006), as well as mechanisms involving the addition of metal ions, lipids, or other factors that enhance the initial unfolding events required for assembly to occur (Yamamoto et al., 2004a; Eakin and Miranker, 2005; Ohhashi et al., 2005; Sasahara et al., 2008). Here, we have shown that  $\Delta$ N6 is a highly amyloidogenic species that is able to nucleate fibrillogenesis efficiently in vitro at neutral pH. This observation rationalizes the lack of circulating  $\Delta$ N6 in the serum of patients with renal dysfunction and, given the natural affinity of  $\Delta$ N6 for collagen (which is enhanced relative to H $\beta_2$ m [Giorgetti et al., 2005]), explains why assembly of fibrils occurs most readily in collagen-rich joints. Additionally, we show that the mild acidification, such as may occur in the synovial fluid of patients undergoing long-term hemodialysis (Relini et al., 2006), has a dramatic effect in

enhancing fibril formation of  $\Delta$ N6 and its ability to convert H $\beta_2$ m into an amyloid-competent state by protonation of His84 and/or other residues in the protein. We propose that rather than being an innocuous postassembly event (Monti et al., 2005), proteolytic cleavage of the N-terminal region of  $\beta_2$ m could be a key initiating event in DRA. Such cleavage enables the formation of species that are not only able to assemble de novo into amyloid fibrils, which thereafter can enhance fibrillogenesis of H $\beta_2$ m by cross-seeding (Figure S5), but when present in only catalytic amounts are also able to convert the wild-type protein into an amyloidogenic state (Figure 5C).

#### Conformational Conversion in Atomistic Detail

A fascinating feature of amyloid fibrils is their ability to consume soluble monomer for self-replication via elongation with their own, or closely related, protein monomers. This suggests that amyloid fibrils or misfolded protein aggregates in general may have an inherent potential to convert innocuous protein conformers into amyloidogenic species, a feature famously associated with prions (Sindi and Serio, 2009). By exploring

**Figure 7. Turning On and Off  $\beta_2m$  Amyloid Assembly**

(A) Summary showing the structures of  $H\beta_2m$  and a model of  $I_T$ . Above, keys for these conformational states. Native  $H\beta_2m$  (leftmost), shown above as a circle with *cis*-X-Pro32 (green I), *trans*-X-Pro14 (blue I), His84 (red circle), and the N-terminal region (residues 1–6, in blue). Upon dissociation of the N-terminal region, the X-Pro32 bond is free to relax into the *trans*-conformation, causing further conformational changes that lead to the formation of the nonnative  $I_T$  conformer (shown as a circle above a model of its structure). Protonation of His84 (shown in red and as a red circle above), which lies adjacent to Pro32 under mildly acidic conditions, further enhances the amyloid potential of  $I_T$ . Oligomerization of these aggregation-prone species then leads to the formation of  $\beta_2m$  amyloid fibrils. Assuming that the fibrils formed at neutral pH are structurally similar to those formed at acidic pH, as suggested by FTIR (Jahn et al., 2008) and solid-state NMR (Debelouchina et al., 2010), large conformational changes are required in order to transform the antiparallel  $\beta$  sheet arrangement of  $\Delta N6$  into the parallel in-register arrangement of  $\beta$  strands characteristic of  $\beta_2m$  amyloid fibrils, as reported recently (Ladner et al., 2010).

(B) Proposed mechanism of conformational conversion of  $H\beta_2m$  into an amyloid-competent state by bimolecular collision with  $\Delta N6$ .  $\Delta N6$  (shown schematically as a circle, using similar color schemes as in A) lacks the N-terminal six residues that clamp  $H\beta_2m$  into its native structure. Protonation of His84 (shown as a red circle [unprotonated] or square [protonated]) occurs at mildly acidic pH. Possibly accompanied by alterations in the conformation/protonation status of other residues, the amyloidogenicity of  $\Delta N6$  is enhanced (Step 1). Bimolecular collision of one or more rarely populated conformers of  $\Delta N6$  with native  $H\beta_2m$  leads to dissociation of the N-terminal region of the latter protein, allowing *cis*-to-*trans* isomerization of X-Pro32 to occur (Step 2). Subsequent protonation of His84 in the wild-type protein is then favored, completing conformational conversion of  $I_T$  (Step 3). Further protein-protein interactions between these species then allow nucleation and elongation of amyloid fibrils (Step 4).

the dynamics and aggregation behavior of  $\Delta N6$ , this study reveals that conformational excursions of  $\Delta N6$ , which occur more frequently upon mild acidification, not only rationalize the inherent amyloidogenicity of this protein but also explain how this species is able to convert  $H\beta_2m$  into an amyloidogenic state. By contrast, transient bimolecular collision between  $\Delta N6$  and  $M\beta_2m$  abolishes the ability of  $\Delta N6$  to convert into amyloid fibrils.

NMR analysis of bimolecular collisions between  $\Delta N6$  and  $H\beta_2m$  (Figures 6A–6D) exposes atomistic details of one possible route of conformational conversion during amyloid formation (Figure 7B). First, protonation of His84 and/or other amino acid side chains of  $\Delta N6$  under mild acidification enhances the aggregation potential of this already amyloidogenic protein (Step 1,

Figure 7B). Next, specific bimolecular collision between  $\Delta N6$  and  $H\beta_2m$  alters the dynamic properties of the AB-loop in  $H\beta_2m$  that contains Pro14, which leads to partial fraying or displacement of the A-strand from the native  $\beta$  sandwich, with concomitant loss of HX protection in this region (Step 2). By this mechanism the X-Pro32 peptide bond becomes free to relax to the *trans*-isomer, triggering the cascade of events involved in the conversion of the constrained native protein to a dynamic amyloidogenic state (Step 3). Further assembly of monomers then leads to the formation of amyloid fibrils via one or more oligomeric species (Step 4). Correct docking of the A strand is thus crucial in trapping the native protein into a unique conformation and maintaining the concentration of amyloidogenic precursor

states below that required for amyloid formation. Exploiting the power of NMR, we reveal here in atomistic detail how a nonnative protein conformer is able to convert an originally innocuous native protein species into an amyloidogenic state, opening the door to protein self-assembly and the onset of amyloidosis.

## EXPERIMENTAL PROCEDURES

### Protein Preparation

Proteins were prepared as previously described (Platt et al., 2005).

### Assembly of Amyloid Fibrils

Samples were prepared in 96-well plates (Corning Incorporated, Costar) containing 0.8–500  $\mu$ M protein, 81–89.5 mM NaCl, 10  $\mu$ M ThT, and 0.02% (w/v) sodium azide in 10 mM sodium phosphate buffer (pH 6.2–8.2). Seeded reactions contained additionally 10% (w/w)  $\Delta$ N6 seeds (see Supplemental Experimental Procedures). De novo fibril growth was performed by incubating the 96-well plate at 37°C, 200 rpm, while seeded reactions were carried out quiescently at 37°C. ThT fluorescence (excitation 440 nm, emission 480 nm) was measured using a plate reader (FLUOstar OPTIMA) at 37°C. The soluble fraction obtained after centrifugation (14,000  $\times$  g, 10 min) was analyzed by SDS-PAGE.

### NMR Spectroscopy and Structure Determination

Samples of  $^{15}$ N- or  $^{13}$ C- $^{15}$ N-labeled protein (0.3–1.0 mM) in 25 mM sodium phosphate buffer pH 7.5, 0.02% (w/v) sodium azide, 90% (v/v)  $\text{H}_2\text{O}/10\%$  (v/v)  $\text{D}_2\text{O}$  were used for NMR experiments.

Spectra were recorded at 25°C on a Varian Inova 500 MHz or 600 MHz instrument with a room temperature probe or a Varian Inova 750 MHz spectrometer equipped with a cryogenic probe. Sequential assignment, structural restraint, structure calculation, and other NMR procedures are detailed in the Supplemental Experimental Procedures online.

### $^{15}$ N NMR Relaxation, Saturation Transfer, and HX Experiments

Backbone  $^{15}$ N transverse relaxation ( $R_2 = 1/T_2$ ),  $^{15}$ N longitudinal relaxation ( $R_1 = 1/T_1$ ),  $\{^1\text{H}\}^{15}\text{N}$  nOe relaxation measurements, and measurements of HX were carried out as described (Farrow et al., 1994; Gorski et al., 2004). Further details are given in the Supplemental Experimental Procedures online.

## ACCESSION NUMBERS

Coordinates and structural restraints of H $\beta_2$ m and  $\Delta$ N6 have been deposited in the PDB and chemical shifts, peak lists, and rdc measurements in BMRB with accession numbers 2XKS and 17165 or 2XKU and 17166, respectively.

## SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, Supplemental References, five figures, and two tables and can be found with this article online at doi:10.1016/j.molcel.2010.11.028.

## ACKNOWLEDGMENTS

We thank David Brockwell and members of the Radford and Homans research groups for helpful discussions and David Eisenberg for providing the M $\beta_2$ m plasmid. We acknowledge, with thanks, the Wellcome Trust (062164 and GR075675MA) and the University of Leeds for funding.
