ABSTRACT

Study question:

Is a clinical trophectoderm (TE) biopsy a suitable predictor of chromosomal aneuploidy in blastocysts?

Summary answer:

In the analyzed group of blastocysts, a clinical TE biopsy was an excellent representative of blastocyst karyotype in cases of whole chromosome aneuploidy, but in cases of segmental (sub-chromosomal) aneuploidy, a TE biopsy was a poor representative of blastocyst karyotype.

What is known already:

Due to the phenomenon of chromosomal mosaicism, concern has been expressed about the possibility of discarding blastocysts classified as aneuploid by pre-implantation genetic testing for aneuploidy (PGT-A) that in fact contain a euploid Inner Cell Mass (ICM). Previously published studies investigating karyotype concordance between TE and ICM have examined small sample sizes and/or have utilized chromosomal analysis technologies superseded by Next Generation Sequencing (NGS). It is also known that blastocysts classified as mosaic by PGT-A can result in healthy births. TE re-biopsy of embryos classified
as aneuploid can potentially uncover new instances of mosaicism, but the frequency of such blastocysts is currently unknown.

**Study design, size, duration:**
45 patients donated 100 blastocysts classified as uniform aneuploids (non-mosaic) using PGT-A by NGS (n=93 whole chromosome aneuploids, n=7 segmental aneuploids). In addition to the original clinical TE biopsy used for PGT-A, each blastocyst was subjected to an ICM biopsy as well as a second TE biopsy. All biopsies were processed for chromosomal analysis by NGS, and karyotypes compared to the original TE biopsy.

**Participants/materials, setting, methods:**
Single IVF center with in-house PGT-A program and associated research laboratory.

**Main results and the role of chance:**
When one or more whole chromosomes were aneuploid in the clinical TE biopsy, the corresponding ICM was aneuploid in 90 out of 93 blastocysts (96.8%). When the clinical TE biopsy only contained segmental (sub-chromosomal) aneuploidies, the ICM was aneuploid in 4 out of 7 cases (57.1%). Blastocysts showing aneuploidy concordance between clinical TE biopsy and ICM were also aneuploid in a second TE biopsy in 86 out of 88 cases (97.7%). In blastocysts
displaying clinical TE-ICM discordance, a second TE biopsy was aneuploid in only 2 out of 6 cases (33.3%).

Limitations, reasons for caution:
All embryos in this study had an initial classification of 'aneuploid' and not 'euploid' or 'mosaic'. Therefore, the findings of this study refer specifically to a TE biopsy predicting aneuploidy in the remaining blastocyst, and cannot be extrapolated to deduce the ability of a TE biopsy to predict euploidy in the blastocyst. No conclusions should be drawn from this study about a mosaic TE biopsy's ability to predict the karyotype of the corresponding blastocyst. Caution should be exercised in generalizing the findings of the sample group of this study to the general IVF blastocyst population. The segmental aneuploidy group only contains 7 samples.

Wider implications of the findings:
The high rate of intra-blastocyst concordance observed in this study concerning whole chromosome aneuploidy contributes experimental evidence to the validation of PGT-A at the blastocyst stage. Concomitantly, the results suggest potential clinical value in reassessing blastocysts deemed aneuploid by TE re-biopsy in select cases, particularly in instances of segmental aneuploidies. This could impact infertility treatment for patients who only have blastocysts classified as aneuploid by PGT-A available.
Study funding/competing interest(s):
This study was supported by the Zouves Foundation for Reproductive Medicine and Zouves Fertility Center. The authors have no competing interest to disclose.

INTRODUCTION

A number of clinical trials have reported improved IVF outcomes following the vetting of embryos for chromosomal abnormalities (Forman et al., 2013; Rubio et al., 2017; Scott et al., 2013; Yang et al., 2012), and yet the IVF community is still debating the appropriate use of preimplantation genetic testing for aneuploidy (PGT-A, previously called PGS) (Practice Committees of the American Society for Reproductive et al., 2018; Sermon et al., 2016). Skeptics of the technology condemn the assumption that a 5-10 cell biopsy is representative of the remaining embryo (Esfandiari et al., 2016; Gleicher and Orvieto, 2017). Indeed, the phenomenon of mosaicism, the condition of containing two or more cell lines with distinct chromosomal content (Taylor et al., 2014), provides a biological rationale for that concern. A karyotypic categorization of the trophectoderm (TE), the precursor to the placenta, might therefore not always be predictive of the inner cell mass (ICM), which gives rise to the fetus.

One of the potential consequences of misclassification of embryos during PGT-A is the deselection of viable embryos when a blastocyst is deemed aneuploid by TE biopsy but in fact contains a euploid ICM (Esfandiari et al., 2016; Schoolcraft et al., 2017; Vera-Rodriguez and Rubio, 2017). Some patients are only capable of producing embryos classified as aneuploid by PGT-A even after repeated IVF cycles, particularly with advanced age (Franasiak et al., 2014). Such cases invariably lead to the abandonment of infertility treatment.
Previous studies investigating rates of TE-ICM chromosomal concordance (expertly reviewed by Capalbo and Rienzi), while extremely valuable, have relied on limited sample sizes or methodologies that have recently been superseded by higher resolution genetic testing platforms (Capalbo and Rienzi, 2017). Next Generation Sequencing (NGS), has been heralded as a PGT-A technique with superior sensitivity for chromosomal mosaicism compared to aCGH, qPCR or SNP array (Fragouli et al., 2017; Harton et al., 2017; Maxwell et al., 2016; Munne et al., 2017; Munne and Wells, 2017) and has also been reported as highly effective in detecting segmental (i.e. sub-chromosomal) losses and gains with higher precision than previous methods (Lai et al., 2017).

The purpose of this study was specifically to test the hypothesis that a blastocyst embryo classified as aneuploid by NGS-based PGT-A correctly predicts the ploidy of the ICM in the majority of cases. Furthermore, by analyzing a second TE biopsy we determined the frequency of blastocysts originally classified as aneuploid that could be redefined as mosaic by re-biopsy.
MATERIALS AND METHODS

Embryos and clinical PGT-A analysis by NGS

Blastocysts derived from patients seeking infertility treatment were generated by in vitro fertilization and embryo culture as previously described (Victor et al., 2017), and were evaluated using the Gardner system (Gardner and Schoolcraft, 1999). As part of the embryo selection process, a clinical 5-10 cell TE biopsy was collected and blastocysts were vitrified. The clinical TE biopsies were subjected to whole genome amplification (WGA) with SurePlex reagents (Illumina) followed by NGS-based PGT-A using Illumina’s VeriSeq kit (Illumina) on a MiSeq system (Illumina) according to the manufacturer’s protocol and described in detail elsewhere (Vera-Rodriguez et al., 2016). For quality control, only samples satisfying the following cutoffs were used: number of Reads Passing Filter: >0.25M; Average Q-Score: >30; Alignment Score: >30; DLR (derivative log ratio): <0.4. Karyotype profiles were evaluated independently by three analysts and consensus determined. Copy number variation (CNV) for each chromosome was scored in Bluefuse Multi Analysis Software (Illumina) according to guidelines defined by the Preimplantation Genetic Diagnosis International Society (PGDIS), accessible at ‘http://www.pgdis.org/docs/newsletter_071816.html’: Profiles with copy number scale values <1.2 and >2.8 were recorded as aneuploid, those with values
between 1.8 and 2.2 were recorded as euploid, and all others were recorded as mosaic. These guidelines reflect the detection range of mosaicism by NGS PGT-A, validated in various cell- and DNA-mixing experiments (Fragouli et al., 2017; Maxwell et al., 2016; Munne et al., 2017; Munne and Wells, 2017). The resolution of VeriSeq NGS is validated to detect segmental (sub-chromosomal) aneuploidies of 20Mb or larger by the manufacturer, although detection of regions down to 1.81Mb have been reported using this platform (Zheng et al., 2015). In our center, we consider ‘aneuploidy’ to encompass both whole and segmental chromosome abnormalities.

Supernumerary blastocysts classified as ‘aneuploid’ (no mosaics) by PGT-A were donated to science by signed informed consent by 45 patients (average age of 36.5 ± 5.7) and de-identified. This study was approved by the institutional review board of the Zouves Foundation for Reproductive Medicine (OHRP IRB00011505).

ICM and Second TE Biopsy Collection and Analysis

ICM biopsies were isolated from vitrified-warmed blastocysts as outlined in the legend for Fig. 1A, basing the technique on a protocol described previously (Taylor et al., 2016) but omitting the exposure of samples to Ca\(^{2+}/Mg^{2+}\)-free medium. Immediately following ICM biopsy an additional TE biopsy was collected. All biopsies were washed three times to clear any loose cells or cellular
debris, and subsequently stored at -80°C until further processing. Biopsies were subjected to NGS-based PGT-A (as detailed above), and results evaluated independently by three analysts blinded to the analysis profile of the original, clinically reported TE biopsy.

For transparency, all karyotype profiles of every biopsy analyzed in this study are shown in the main or supplemental figures of the manuscript.

**Immunofluorescence**

Whole blastocysts or biopsies were immersed in fixation buffer containing 4% paraformaldehyde (EMS #15710) and 10% fetal bovine serum (FBS) (Seradigm 1500-050) in phosphate buffered saline (PBS) (Corning MT21040CM) for 10 minutes (min) at room temperature (rt), followed by three 1 min washes at rt in stain buffer, composed of 0.1% Triton X-100 (TX-100) (Sigma X100-100ML) and 10% FBS in PBS. Samples were then immersed in permeabilization buffer (0.5% TX-100, 10% FBS in PBS) for 30 min at rt, followed by three washes in stain buffer. Samples were then exposed to stain buffer containing both primary antibodies each in 1:200 concentrations over night at 4°C rocking on a nutator. Primary antibodies were mouse anti-human GATA3 (Thermo Fisher MA1-028) and rabbit anti-human OCT4A (Cell Signaling #2890). The next day, after three washes in stain buffer, samples were immersed in stain buffer containing both secondary antibodies each in 1:500 concentrations for 2-3 hours at rt. Secondary
antibodies were goat anti-mouse IgG AlexaFluor488 (Thermo Fisher A11029) and goat anti-rabbit IgG AlexaFluor647 (Thermo Fisher A21245). After three washes in stain buffer, samples were exposed to nuclear stain (Hoechst 33342, Thermo Fisher H3570) diluted at 1:1000 in stain buffer for 30 min at rt, followed by three more washes in stain buffer. Samples were placed in glass bottom dishes (MatTek P35G-1.5-20-C) in small drops of stain buffer overlaid with mineral oil (Sigma M5904), and imaged with a LSM 780 Confocal microscope (Zeiss).

Analysis of tissue relatedness

In cases of clinical TE-ICM karyotype discordance we confirmed tissue relatedness by a DNA fingerprinting method that utilizes SNP analysis and linkage disequilibrium known as ‘Tilde’ (Vohr et al., 2015). A full explanation of the adaptation of this method to PGT-A samples with low coverage NGS is detailed in Supplemental Data 1.

Statistical analysis of correlation between morphology and karyotype discordance

Analysis and graph preparation were performed in Prism 6 (GraphPad). Differences between groups were assessed by Chi-square test for trend with 95% confidence levels. Significance was defined when P < 0.05.
RESULTS

Isolation of ICM and Second TE Biopsies

We adopted a modified ICM-biopsy procedure previously outlined (Taylor et al., 2016), which permitted us to collect an ICM biopsy and subsequently a second TE biopsy in blastocysts (Fig. 1A and Video 1). Immunofluorescence was used to confirm accurate isolation of intended cells. In whole blastocysts the pluripotency factor OCT4 was present at high levels in the ICM and low levels in the TE, while GATA3 was exclusively expressed in cells of the TE as previously shown (Deglincerti et al., 2016). Analysis of matched TE-ICM biopsies from 12 blastocysts indicated that both biopsy types exclusively contained cells of their intended lineage and were devoid of contamination from the other cell type (Fig. 1B and Supplemental Fig. 1). Nuclear counterstain by Hoechst did not reveal any cells with fragmenting or apoptotic nuclear material, suggesting that the biopsy technique did not disrupt individual cells (Fig. 1B and Fig. S1). On average, TE biopsies comprised 7.6 cells (+/- 1.3 SD) while ICM biopsies comprised 7.3 cells (+/- 2.0 SD).

Clinical TE-ICM Biopsy Concordant Blastocysts

Of the 100 blastocysts originally classified as aneuploid by clinical (original) TE biopsy, 93 had ICMs that were also classified as aneuploid, which we denote as aneuploid-aneuploid concordant (Fig. 2 and Table I). Importantly,
when only considering blastocysts with whole chromosomal aneuploidies (single or multiple) in their clinical TE biopsies, aneuploidy in the ICM was present in 90 out of 93 cases (96.8%). On the other hand, when considering blastocysts with only segmental (sub-chromosomal) aneuploidies in their clinical TE biopsies, aneuploidy in the ICM was present in only 3 out of 7 cases (42.9%).

In aneuploid-aneuploid concordant blastocysts, analysis of second TE biopsies showed aneuploidy in 86 out of 88 cases, equaling 97.7% (Table I). The remaining two samples showed a mosaic pattern in their respective second TE biopsies. In five samples a second TE biopsy could not be retrieved.

The 93 clinical TE-ICM aneuploid-aneuploid concordant blastocysts could be further subdivided in two groups. 79 were blastocysts that had perfectly matching karyotypes in the clinical TE and ICM biopsies (i.e., all the same chromosomes possessed the same aneuploidies in both tissues), which we denoted as aneuploid-aneuploid perfect concordant (Fig. 2, Table I, and for the karyotypic profiles see Supplemental Fig. 2). Such instances are likely consequences of meiotic errors, as the identical aneuploidy is present in both TE and ICM tissues (see Supplemental Data 2 for more detailed interpretations).

The remaining 14 out of 93 blastocysts had dissimilar aneuploidies in the clinical TE and ICM biopsies, which we denoted as aneuploid-aneuploid imperfect concordant (Fig. 2, Table I, and for the karyotypic profiles see Supplemental Fig. 2). Interestingly, most such blastocysts (10 out of 14) showed the same aneuploid chromosome(s) in the ICM biopsy as the clinical TE biopsy.
(presumed consequence of meiotic error), but contained additional mosaic
events in the ICM (resulting from mitotic error), often segmental in nature.
See Supplemental Data 2 for interpretations of chromosomal error
etiologies in samples of the aneuploid-aneuploid *imperfect* concordant group.

**Clinical TE-ICM Biopsy Discordant Blastocysts**

Of the 100 blastocysts tested, we observed two cases in which the clinical TE biopsy was uniformly aneuploid but the ICM was mosaic (Fig. 2, Table I, and for the karyotypic profiles see Fig. 3). Supplemental Data 2 contains more detailed interpretations of their karyotypes.

Five out of 100 blastocysts had euploid ICMs while their clinical TE biopsies contained aneuploidies (Fig. 2, Table I, and for the karyotypic profiles see Fig. 3). Blastocyst #96 was the only case in which the clinical TE biopsy had a whole chromosomal aneuploidy (gain of chromosome 12, note that the karyotype profile enters into the 2.8-3.0 copy number region) but displayed euploidy in the ICM as well as in the second TE biopsy.

The remaining four samples (blastocysts #97-#100) contained segmental aneuploidies in their original TE biopsies, but euploid ICM biopsies. For blastocyst #97, the clinical and second TE biopsies contained the same segmental aneuploidy, thereby suggesting euploidy confined to the ICM. This would be consistent with a mitotic event happening before or at the time of lineage segregation but in the progenitor cell of a large part of the TE.

Blastocysts #98 and #99 displayed mosaicism in their respective second TE
biopsies, revealing the occurrence of mitotic errors in the TE lineage. For one blastocyst (#100), the second TE biopsy did not yield results due to a failed WGA reaction. (Global WGA failure rate for this study is 1 out of 221, or 0.4%). In total, of the clinical TE-ICM discordant blastocysts (aneuploid-euploid or aneuploid-mosaic) yielding information in the second TE biopsy, only 2 out of 6 (33.3%) were uniformly aneuploid.

In cases of clinical TE-ICM biopsy discordance, there existed the possibility of sample contamination or mislabeling. Notably, in the 100 embryos tested, the sex chromosomes (XX or XY) were always concordant between biopsies taken within the same blastocyst. Further, for each of the seven blastocysts that produced discordant results, we performed DNA fingerprinting to confirm that the clinical TE and ICM biopsies were derived from the same respective embryos (Fig. 4 and Supplemental Fig. 3).

Finally, we determined whether poor blastocyst morphology impacted karyotype discordance. The analysis indicated that neither blastocyst stage nor ICM/TE grade affected the likelihood of intra-blastocyst karyotype inconsistencies (Supplemental Fig. 4).
DISCUSSION

Some parties have argued that PGT-A should not be performed under any circumstance and one of the criticisms of the technology questions whether a clinical TE biopsy is a valid genetic representative of the embryo (Esfandiari et al., 2016; Mastenbroek and Repping, 2014; Sermon et al., 2016). A study basing its rationale on mathematical modeling has claimed that a typical TE cell biopsy cannot determine embryo ploidy accurately enough for clinical use (Gleicher et al., 2017). One of the ensuing concerns that has been expressed is the possibility of erroneously discarding viable embryos (Practice Committees of the American Society for Reproductive et al., 2018). Here however, we provide experimental evidence using NGS that a TE biopsy classified as aneuploid is commonly predictive of aneuploidy in the ICM. In our experience, a whole chromosome aneuploidy in a clinical TE biopsy is predictive of aneuploidy in the ICM in 96.8% of cases (sample size n=93), although for a segmental aneuploidy this decreases significantly to 42.9% (n=7).

A blastocyst with an aneuploid TE and ICM due to meiotic error is in principle exceptionally unlikely to result in healthy pregnancy (Adashi and McCoy, 2017). Although various corrective mechanisms for aneuploidies in human embryos have been proposed (differential proliferation/depletion, preferential lineage allocation, self-correction) (Capalbo and Rienzi, 2017; McCoy, 2017) and have also been conceptually demonstrated in mouse embryos (Bolton et al., 2016) and human embryonic stem cells (hESC) (Munne et al.,
most models describe the out-competition of aneuploid cells by euploid cells in the mosaic setting, not the conversion of an entirely aneuploid embryo to an entirely euploid one.

The observation that segmentals had a drastically different rate of clinical TE-ICM discordance compared to whole chromosome aneuploids highlights the difference in mechanistic origins of these two types of aneuploidies. Whole chromosome aneuploidies can arise during meiosis or mitosis by different mechanisms that include non-disjunction, anaphase lag, and endoreplication (Taylor et al., 2014), but the majority are believed to be derived from meiotic errors in the oocyte (Nagaoka et al., 2012). The majority of segmental aneuploidies on the other hand are mitotic in origin and are thought to arise during the first few cell divisions after fertilization (Babariya et al., 2017). Cell cycle control is thought to be more lax during the first days of embryogenesis due to rapid mitoses primarily controlled by maternal RNA and proteins, leading to an increased incidence of double strand breaks which upon faulty correction mechanisms result in segmental duplications or deletions when left unresolved by a strained cell cycle machinery (Babariya et al., 2017). Consequently, segmental aneuploidies will often be represented in mosaic configurations at a whole blastocyst level, likely translating in the high TE-ICM discordance rate observed for the segmental aneuploidy group in this study.

Out of 93 blastocysts with whole chromosome aneuploidies (single or multiple) in a clinical TE biopsy, three embryos had a discordant ICM: two contained mosaic ICM biopsies, and one had a euploid ICM. Consequently, the
18

karyotype of these three blastocysts should be re-classified from aneuploid to
mosaic, since on a whole embryo level they contained aneuploid and euploid
cells. This re-categorization would have changed the status of the blastocysts
from ‘not recommended for transfer’ to ‘possible transfer if no euploid embryos
available’. Mosaic embryos have recently been considered for transfer in several
clinics, producing healthy pregnancies albeit with considerably lower implantation
rates than blastocysts classified as euploid (Fragouli et al., 2017; Lledo et al.,
2017; Munne et al., 2017; Spinella et al., 2018).

From a clinical standpoint, our findings may support re-biopsy of
blastocysts in patients that have only produced embryos classified as aneuploid
(particularly segmentals) by initial TE biopsy after repeated IVF cycles, an
occurrence that happens with relative frequency especially with advanced
maternal age (Franasiak et al., 2014). It could also affect those patients that have
unsuccessfully transferred their embryos classified as ‘euploid’ and ‘mosaic’, and
only have ‘aneuploid’ samples remaining. In our study, all blastocysts had an
initial, clinical TE biopsy that was uniformly aneuploid. When a second TE biopsy
was either mosaic or euploid, such a blastocyst had a 66% chance to contain an
ICM that was either mosaic or euploid as well. On the other hand, in cases where
the second TE biopsy was aneuploid, the ICM was mosaic in only 1.1% of cases,
and there were no euploid ICM instances. Therefore, our results suggest that TE
re-biopsy can reveal whether the ICM is mosaic or euploid, helping to identify
new blastocysts for possible clinical use that were originally not recommended
for transfer due to aneuploidy in the clinical TE biopsy. Importantly, while the act
of re-biopsy might negatively affect blastocysts, re-biopsied blastocysts can lead
to healthy pregnancies albeit with lower efficiency than single-biopsied
blastocysts (Bradley et al., 2017). Nevertheless, more research is necessary to
determine the short and long term effects of TE re-biopsy, and recommendation
of routine re-biopsy of blastocysts classified as aneuploid is undoubtedly
premature.

The confirmed existence of clinical TE-ICM discordant embryos could also
help explain the rare accounts of healthy pregnancies resulting from transfer of
embryos classified as aneuploid by PGT-A (Gleicher et al., 2016), although it
must be pointed out that to our knowledge, there exist no reports of such events
when using blastocyst stage NGS-based PGT-A.

It is important to note that our determined rates of clinical TE-ICM
concordance apply specifically to blastocysts classified as ‘uniform aneuploid’ (no
mosaics) by PGT-A. Having observed an overall 7% clinical TE-ICM discordance
rate in our samples, we cannot assume the inverse: that 7% of blastocysts
classified as euploid contain an aneuploid ICM. A further intriguing and clinically
important question is what a clinical TE biopsy showing mosaicism says about
the ICM. Unfortunately, our study cannot shed light on that point.

A further limitation of this study was that not all cells were analyzed for
intra-blastocyst karyotypic concordance. The ICM biopsies isolated (averaging
7.3 cells) collected the bulk of ICM cells but invariably left residual ICM cells
behind. On average, we collected 15 TE cells from the two combined TE biopsies
of each blastocyst, hence a substantial portion of the TE was left unanalyzed.
From the technical standpoint we were unable to isolate more cells from a specific tissue without contamination from the other lineage. As a result, instances of karyotype discordance could remain concealed.

While highly controversial, the concept of transferring embryos testing aneuploid by PGT-A is a real subject of discussion in both scientific (Gleicher et al., 2016) and mainstream media (Hall, 2017). The upheaval created by these viewpoints has partly been bolstered by the yet unspecified capability of a single clinical TE biopsy to reflect the state of the ICM and remaining TE. With regard to this question our findings contribute experimental validation on the practice of PGT-A at the blastocyst stage, considering the high intra-blastocyst aneuploidy concordance rates, especially in the case of whole chromosome losses or gains.

If indeed the group of blastocysts analyzed in this study is representative of the general body of IVF blastocysts, it would mean that when selecting an embryo classified as 'aneuploid' by PGT-A for uterine transfer, it almost always contains aneuploidy in the entire blastocyst. Unless robust self-correction mechanisms do in fact exist, said embryo would invariable lead to failed implantation, miscarriage, or chromosomally abnormal babies. Segmental aneuploidies on the other hand are rarely concordant; if our observations are confirmed in a larger sample group they should be regarded as their own distinct class when prioritizing or de-selecting embryos for transfer in the clinic.

FIGURE LEGENDS

Figure 1.

Validation of biopsy and PGT-A methods used in the study

(A) Stills from video depicting isolation of ICM biopsy in blastocysts. The blastocyst is immobilized with a holding pipet touching the polar TE (adjacent to the ICM), and laser pulses are administered through the zona and mural TE opposite the ICM creating an opening. A biopsy pipette is introduced and guided to the ICM, which is suctioned out through the opening. Once a portion of ICM cells are extracted past the zona, they are exposed to laser pulses aimed at cell-cell junctions to isolate a 5-10 cell biopsy.

(B) Nuclear counterstain (Hoechst) and immunofluorescent stains for the TE marker GATA3 and ICM marker OCT4 in a whole human blastocyst and isolated TE and ICM biopsies. See additional samples in Figure S1. Scale bars = 25µm.
Figure 2.

Summary of paired clinical TE-ICM comparison results

Dot plot displays results for all blastocysts, regardless of aneuploidy type. Pie charts depict data stratified by nature of aneuploidy detected in the original TE biopsy for each blastocyst.

Supplemental Figure 4

Analysis of correlation between morphology and intra-blastocyst karyotype discordance

Blastocysts were evaluated using the Gardner system, that assigns a number score for blastocyst expansion stage (1-6 from least to most progressed), and letter scores for ICM and TE grades (C-A from worst to best quality) (Gardner and Schoolcraft, 1999). Stage of blastocyst was analyzed when there was any intra-blastocyst karyotype inconsistency (A), when an inconsistency was specific to the ICM (B), and when an inconsistency was specific to the TE (C). Grade of the ICM was analyzed when there was any karyotype inconsistency between clinical TE biopsy and the ICM (D). Grade of the TE was analyzed when there was any karyotype inconsistency between clinical TE and second TE biopsy (E). Note that in graphs A, C, and D, sample numbers do not add up to 100 because in six cases the second TE biopsy was not processed (in five cases the biopsy could not be collected, and in one case there was a failed WGA reaction.)

Supplemental Data 1

Analysis of tissue relatedness

‘Tilde’ (Vohr et al., 2015) was used to rule out sample cross-contamination or mislabeling and infer, based on low-coverage sequencing data, whether ICM and TE biopsies were derived from the same blastocyst. This method facilitates indirect comparison of low-coverage samples based on the principle that sparse observed genotypes are informative of genotypes at nearby unobserved markers due to patterns of linkage disequilibrium (LD) in the population.

Reads were mapped to the hg19 reference using the BWA (version 0.7.17) backtrack algorithm with default parameters (Li and Durbin, 2009). We then used the LASER method (version 2.04; (Wang et al., 2015)) to select the appropriate ethnically matched 1000 Genomes Project super-population (Genomes Project et al., 2015) for each blastocyst, as required by tilde. LASER combines genotype imputation with principal components analysis to infer individual ancestry based on low-coverage sequence data. Blastocyst genotypes were visualized in reference ancestry space defined by principal components analysis of the HGDP reference panel (Supplemental Fig. 4; (Li et al., 2008)). Blastocysts were then assigned to corresponding 1000 Genomes super-populations based on ancestries of the K=10 nearest neighbor reference samples in principal components space (Supplemental Table I). In the case of
blastocyst #97, whose ICM and TE biopsies were assigned to European and Middle Eastern reference populations, respectively, we selected the European super-population as the reference panel. We note that these populations fall close to one another in space defined by the top three principal components. Furthermore, Vohr et al. (2015) demonstrated that tilde is relatively robust to misspecification of the reference panel.

Tilde computes a log-likelihood ratio comparing a model in which two samples are derived from the same individual (i.e., same embryo) to a model in which two samples are derived from unrelated individuals (i.e., different embryos). Positive log-likelihood ratios indicate that the data support the former model, while negative log-likelihood ratios indicate that the data support the latter model. Bootstrapping was performed to generate distributions and assess uncertainty in log-likelihood ratio estimates.

As controls, we applied this method to twenty-four comparisons of presumed unrelated embryos as well as four comparisons of full sibling (full-sib) embryos obtained from the same patient. Results from the unrelated negative controls supported the capacity of tilde to distinguish these samples, reflected by negative distributions of log-likelihood ratios (Fig. 4). For all seven embryos producing discordant TE-ICM results, the data supported a model in which the samples were derived from the same corresponding embryo, reflected by positive distributions of log-likelihood ratios. Meanwhile, the full-sib samples from the same patient also produced positive distributions of log-likelihood ratios, but intermediate between the unrelated and same-embryo comparisons, supporting
the power of tilde to distinguish varying levels of relatedness. Together, our data suggest no evidence of cross-contamination or sample mislabeling and substantiate the conclusion that the TE and ICM biopsies of discordant karyotype were derived from the same respective embryos. More generally, our analysis demonstrates that methods such as tilde, which take advantage of patterns of LD in the population, can be useful for research on low-coverage sequencing-based PGT-A datasets.
