30

31 **Abstract**

32

33 The physical arrangement of chromatin in the nucleus is cell type and species specific; a fact

34 particularly evident in sperm, in which most of the cytoplasm has been lost. Analysis of the

35 characteristic falciform ('hook shaped') sperm in mice is important in studies of sperm

36 development, hybrid sterility, infertility and toxicology. However, quantification of sperm

37 shape differences typically relies on subjective manual assessment, rendering comparisons

38 within and between samples difficult.

39

40 We have developed an analysis program for morphometric analysis of asymmetric nuclei

41 and characterised the sperm of mice from a range of inbred, outbred and wild-derived

42 mouse strains. We find that laboratory strains have elevated sperm shape variability both

43 within and between samples in comparison to wild-derived inbred strains, and that sperm

44 shape in F1 offspring from a cross between CBA and C57Bl6J strains is subtly affected by

45 the direction of the cross. We further show that hierarchical clustering can discriminate

46 distinct sperm shapes with greater efficiency and reproducibility than even experienced

47 manual assessors, and is useful both to distinguish between samples and also to identify

48 different morphological classes within a single sample.

49

50 Our approach allows for the analysis of nuclear shape with unprecedented precision and

51 scale and will be widely applicable to different species and different areas of biology.

52

Introduction

Cell nuclei are complex, dynamic structures that can adopt a wide range of shapes beyond simply spherical [1]. One of the most profound changes to nuclear shape occurs in spermatogenesis, during which the nucleus successively reshapes and condenses [2,3]. Most rodents, including mice, have elaborate falciform 'hook-shaped' sperm, with varying degrees of hook length and body shape between species [4]. The mouse sperm head shape is established via the interaction of several distinct developmental 'modules', each of which relates to particular cytoskeletal components [5]. When these processes go awry, distinct morphological abnormalities can result (e.g. [6]), linking phenotype with the underlying genetic alterations.

Mouse sperm shape analysis has proven useful in three interrelated areas: evolutionary biology (including speciation), infertility and toxicology. In evolutionary biology, the questions of how evolutionary forces such as sperm competition and cryptic female choice affect sperm form and function are active fields of research [7,8], while the high degree of between-species morphological variability means that morphometric analysis can at times aid in species identification [9]. Relatedly, altered regulation of reproductive processes in inter-species hybrids is common, with hybrid males frequently showing highly pleomorphic sperm. The degree to which this morphological instability contributes to speciation-associated process such as hybrid male sterility is also an open question [10]. In particular, in house mouse hybrid sterility, a range of mapped quantitative trait loci have been identified on on both gonosomes and autosomes that affect both sperm morphology and hybrid sterility [11–14]. In both clinical semen analysis and in mouse knockout models, altered sperm morphology is commonly associated with infertility. However, the role played by specific types and extents of shape defect remains to be elucidated, as does the extent to which teratozoospermia can be used as an indicator of other sperm defects such as DNA

80 damage or defective motility [15]. In toxicology, sperm shape is frequently used as an

81 assessment of genotoxicity and/or reproductive toxicity of compounds (e.g. [16,17]).

82

83 While much sperm analysis still relies on time-consuming and subjective manual scoring,

84 various efforts have been directed towards the development of automated morphometric

85 analyses in an effort to improve both reproducibility and predictive value. To date, these

86 approaches have fallen into three main groups: the measurement of basic parameters such

87 as lengths, widths, and areas of objects; the use of elliptic Fourier analysis to investigate the

88 two dimensional outlines of sperm; and the use of Procrustes analyses to examine

89 differences in fixed landmarks within sperm heads. Each has advantages and

90 disadvantages.

91

92 Basic measures such as area (A), length (L), width (W) and perimeter (P) were the first

93 statistics recorded describing sperm morphology (e.g. [18–20]), and still remain useful when

94 an assessment of semen quality must be made rapidly across many different cells [21].

95 However, such parameters are dominated by the size of the object rather than the shape,

96 and do not allow consistent assessment of the number of normal sperm across populations

97 [22]. Size-independent descriptors can subsequently be constructed from these basic

98 lengths, e.g. L/W ratio (ellipticity) or W/L ratio (aspect ratio). Comparison of linear

99 dimensions to area (e.g. circularity, also known as rugosity or roughness) allow a basic

100 measure of the complexity of the sperm outline, but the values obtained are generic

101 descriptors that cannot be clearly linked to specific elements of the sperm ultrastructure.

102 More powerful elliptic Fourier descriptors [23] allow an arbitrary closed two dimensional

103 shape to be decomposed into harmonic amplitudes describing the curvature of the object

104 perimeter, allowing subtle variations in shape to be discovered [24]. This has proved

105 powerful for demonstrating differences between species, between laboratory strains, and

106 different experimental treatments (e.g. [25–27]), but has the drawback that both the shape

107 parameters and the underlying mathematics are difficult for biologists to understand and

108 relate back to the biological structure that is affected [28]. Moreover, since Fourier analyses

109 rely on smooth harmonic deformations of an underlying elliptical outline, sharp points - such

110 as found at the tip of a mouse sperm - tend to be poorly fitted [29].

111

112 The third major method, Procrustes-based geometric morphometric analysis, uses

113 landmarks and semilandmarks within the object to align individual samples to consistent

114 size, position and orientation (e.g. [4,30]). Principal component analysis (PCA) can then be

115 used to identify the major varying landmarks distinguishing samples [5]. This approach has

116 the advantage of relating the measured variation to physical structures within the object;

117 however, since objects are aligned by a least-squares method rotating about the centroid,

118 objects are susceptible to smearing of landmarks in highly variable regions, and usually

119 require time-consuming manual placement of landmarks.

120

121 To address the unmet need for rapid, unbiased measurement, analysis and categorisation of

122 nuclear morphologies, we have developed a new image analysis tool that automates object

123 finding, alignment, landmark discovery and sample comparison. This generates quantitative

124 information on the underlying regions of the nucleus that differ within and between samples,

125 independent of nuclear size. Here, we demonstrate the use of this software for each of these

126 approaches by comparing a range of different inbred, outbred and wild-derived mouse

127 strains, quantifying the morphological variation in highly pleomorphic BALB/c sperm

128 samples, and tracing the genetic influences on sperm morphology in a reciprocal F1 cross

129 between CB57Bl6 and CBA strains.

130

Materials and Methods

Mouse strains

All animal procedures were in accordance with the United Kingdom Animal Scientific Procedures Act 1986 and the University of Montana Institute for Animal Care and Use Committee (protocol 002-13) and were subject to local ethical review. Animals were sourced either from an approved supplier (Charles River Laboratories, Manston, UK), bred at Cambridge University Central Biomedical Services (Home Office licenses 80/2451 and 70/8925 held by PE), or bred at the University of Montana (Table 1). Breeding colonies at the University of Montana were established from mice purchased from Jackson Laboratories (Bar Harbor, ME) or were acquired from Francois Bonhomme (University of Montpellier). Animals were housed singly or in small groups, sacrificed via CO2 followed by cervical dislocation (UM) or only cervical dislocation and tissues collected post mortem for analysis.

Sperm collection and fixation

The vasa deferentia and caudae epididymides were dissected from each animal, and the contents squeezed out into 1ml PBS (scaled accordingly if multiple animals were pooled). Sperm were transferred to a microfuge tube, and tissue clumps were allowed to settle. Sperm were transferred to a new tube and pelleted at 500g for 5mins. The supernatant was removed, and sperm fixed dropwise with either 3:1 methanol-acetic acid or 2% paraformaldehyde (PFA) in PBS. Sperm were pelleted at 500g for 5mins, washed in fixative twice more, then stored at -20°C (methanol-acetic acid) or 4°C (PFA).

155

156 *Imaging*

157

158 Samples were diluted in fixative as required to obtain an evenly-spread preparation, and 8µl

159 of sample dropped onto a slide and allowed to air dry. Slides were stained with 16µl

160 VectorShield with DAPI (Vector Labs) under a 22x50mm cover slip and imaged using an

161 Olympus UPFLN100XOI2 100x oil immersion plan semiapochromat objective (NA 1.30) on

162 an Olympus BX-61 epifluorescence microscope equipped with a Hamamatsu Orca-ER

163 C4742-80 cooled CCD camera and appropriate filters. Images were captured using Smart-

164 Capture 3 (Digital Scientific UK). To validate the reproducibility of the software, sample

165 images were also gathered on three other microscopes: (1) an Olympus BX61 with a

166 Hamamatsu C10600 orca r² camera, (2) an Olympus BX61 with a Hamamatsu Orca-03G

167 camera (both (1) and (2) using an Olympus UPFLN100X 100x oil immersion plan

168 semiapochromat objective (NA 1.30)), and (3) a Nikon Microphot-SA epifluorescence

169 microscope using a Nikon 100x oil immersion plan apochromat objective (NA 1.40) with a

170 Photometrics Metachrome II CH250 cooled CCD camera.

171

172 *Nucleus detection and morphological analysis*

173 Image analysis was performed using a custom program designed as a plugin for the freely

174 available image analysis program ImageJ [31]. The software is available at

175 http://bitbucket.org/bmskinner/nuclear_morphology/wiki/Home/ together with full installation

176 instructions, an online wiki user manual, and example testing images. Analyses were

177 conducted using software version 1.14.1. The software allows a user to select a folder of

178 TIFF images previously captured using a fluorescence microscope, and interactively define

179 the nucleus detection parameters. The program then automatically detects and analyses the

180 nuclei in the images.

181

182 Once nuclei are acquired from a set of images, they are consistently oriented and aligned.

183 Landmarks are automatically identified using a modification of the Zahn-Roskies (ZR)

184 transform [32] to generate a linear trace we refer to as the angle profile (Figure 1). The

185 conventional ZR transform approximates a given shape as a polygon based on a fixed

186 number of semilandmarks spaced evenly around the perimeter of the shape, and then

187 measures the angle at each vertex of the resulting polygon [4]. In our analyses, we measure

188 the interior angle across a window of 5% of the total object perimeter – equivalent to a ZR

189 transform with 20 semilandmarks per object. This window size was chosen to be maximally

190 informative, following testing of a range of values (Supplementary Figure 4). However, in

191 contrast to the ZR transform that uses a single set of semilandmarks per object and only

192 measures the angle at each semilandmark, we instead measure the interior angle at every

193 point around the shape's perimeter. The final result is thus equivalent to combining multiple

194 overlapping ZR transforms, each offset by a single point so as not to duplicate or lose

195 information. We find this to give a higher-resolution encoding of the shape that loses less

196 information in finely-detailed areas such as the hook tip and tail attachment site.
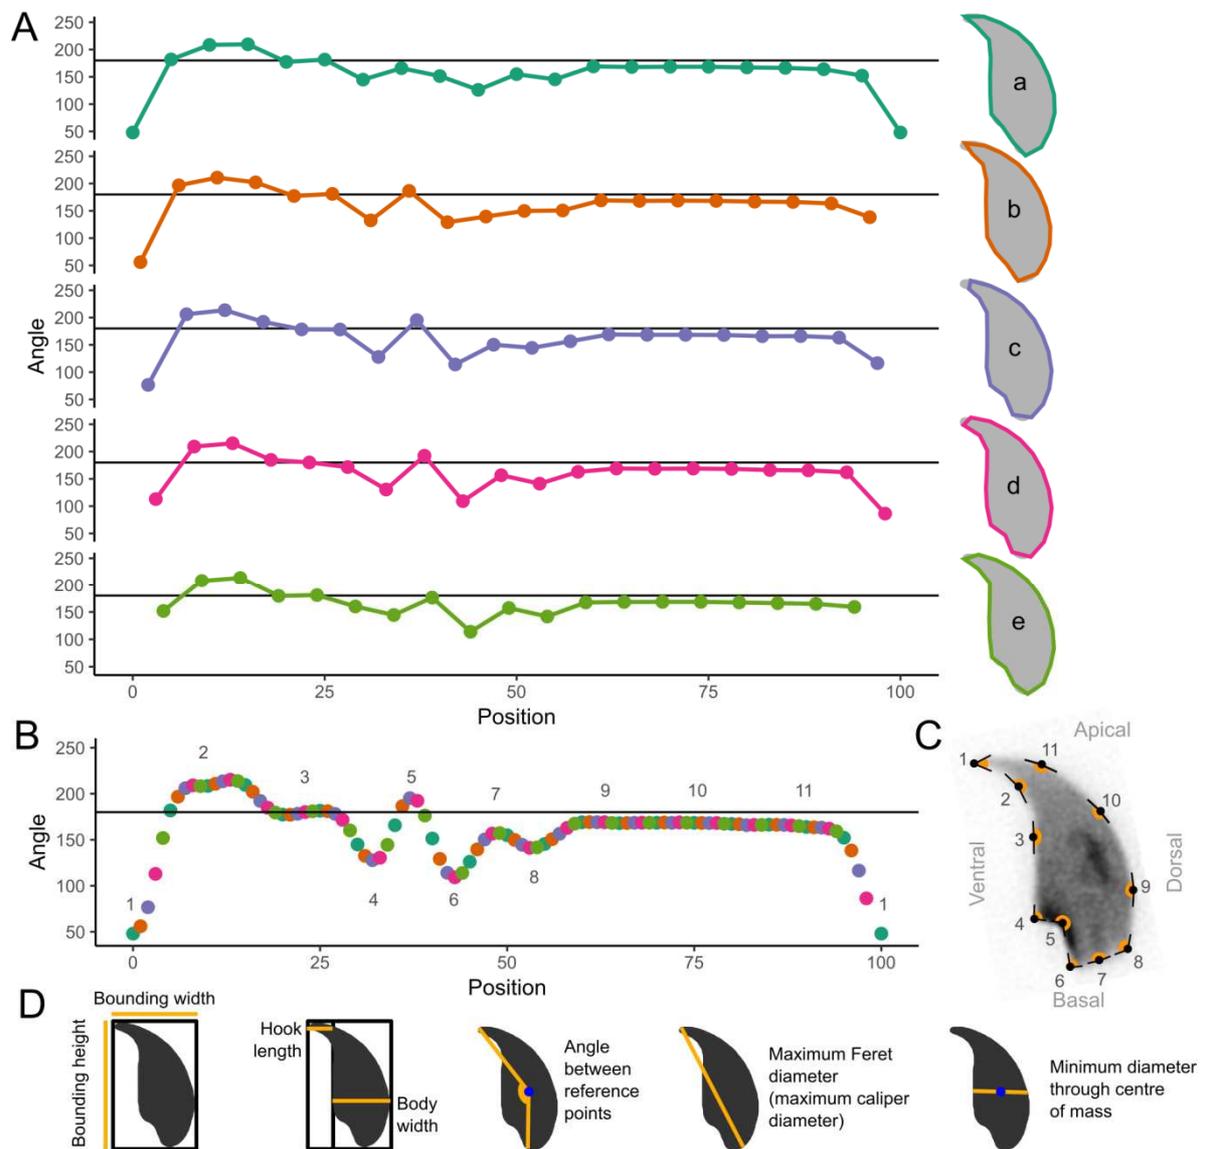

Figure 1: Landmarks are detected by measuring the internal angles around the periphery of the nuclei. A) The Zahn-Roskies method is based on approximating the true curved shape as a lower-resolution polygon with fixed side lengths. The same underlying curve can be encoded multiple ways (a - e) depending on where the vertices of the polygon fall in relation to the underlying shape. For example, the tip is detected well in (a), but not the tail socket; the reverse is true in (d). No individual encoding captures all nuclear features. B) We measure the angle at every individual pixel around the original shape. This method combines the data from every possible polygonal approximation into a single unified trace, from which landmark features can be detected. (C) Features are marked on a nucleus; 1 - tip; 2 - under-hook concavity; 3 - vertical; 4 - ventral angle; 5 - tail socket; 6 - caudal bulge; 7 - caudal base; 8 - dorsal angle; 9-11 - acrosomal curve. D) Definitions of key measured parameters used in the software from Table 2. The nucleus centre-of-mass is a blue dot. Automatic vertical orientation is used to determine bounding dimensions.

The angle profiles from each nucleus are interpolated to a consistent length and aligned

214   against other. A median profile is constructed by taking the median of the angles at each

215   point along the interpolated profile length. The median profile is segmented at local mimima

216   and local maxima below or above 180 degrees respectively, automatically defining

217   landmarks at convex or concave corners in the shape. The landmark locations in each

218   nucleus are then identified via the best fit of the nucleus profile to the median at each

219   landmark. The flat region below the hook is used to allow consistent vertical orientation of

220   the nuclei. A diagram of the full analysis pipeline is provided as Supplementary Figure 1.

221   *Statistical analysis and clustering*

222

223   Following segmentation, standard nuclear parameters are automatically measured: area,

224   perimeter and ellipticity, the width of the nuclear body versus the length of the hook as

225   described in other papers [20], and the lengths of each perimeter segment (Table 2, Figure

226   1D). In order to quantify the variability of the nuclear shapes, we developed a new per-

227   nucleus measure defined as the root-mean-square difference between the per-nucleus angle

228   profile and the median angle profile for the dataset, after interpolation to a fixed length.

229   Summary statistics are automatically calculated.

230

231   Data was exported for further processing in R. Differences between mouse strains were

232   tested using a pairwise Wilcoxon rank sum test, with Bonferroni multiple testing correction.

233   The coefficient of variability (standard deviation / mean) was also calculated for each of the

234   other measured parameters.

235

236   The 'average shape' of the nuclei was calculated by averaging the x and y coordinates at

237   consistent semilandmarks spaced every 1% of the perimeter across all nuclei, vertically

238   aligned and with their centres of mass at (0,0). This yielded a 'consensus nucleus'

239   visualising the overall shape of the population. Clustering was implemented via the WEKA

240   data mining software library [33].

241

242

Results

Morphology analysis is robust to image capture conditions

Before investigating the biological differences between samples, we needed to be confident

that our analyses were reproducible and not biased by small differences in data gathering -

for example, the camera and microscope used to capture images, and the exposure time

during image capture. The choice of fixative (3:1 methanol:acetic acid [MeAc] vs 2%

paraformaldehyde [PFA]) did not affect overall shape (Supplementary Figure 7), but had a

minor and inconsistent effect on sperm head area (Supplementary Figure 8). We

standardised on paraformaldehyde fixation for the remainder of our analyses. The objective

lens and camera did not affect our results (Supplementary Figure 9), and automatic

exposure time produced images equal to an optimised fixed exposure time (Supplementary

Figure 10). We standardised on data from a single microscope using automatic exposure

times for the subsequent image capturing.

Detection and quantification of sperm shape in C57Bl6 and CBA mice

CBA and C57Bl6 sperm are distinguishable to the trained eye, and make a useful

demonstration of the software, as the angle profiles generated are distinct for each genotype

(Figure 2A). CBA sperm have a larger cross-sectional area, are longer, and also have

slightly shorter hooks than C57Bl6 sperm (Figure 2B/C). These differences are reflected in

the profiles; the long narrow tail in the CBAs appears as a smooth curve at x=50 in the

profile, while the shorter, wider C57Bl6s show a distinct dip corresponding to the sharper

265   curve of the dorsal angle before the acrosome. The shorter hook of the CBAs is also seen as

266   a narrow peak at x=10; a detailed comparison of segmentation patterns is given in

267   Supplementary Figure 11.

268
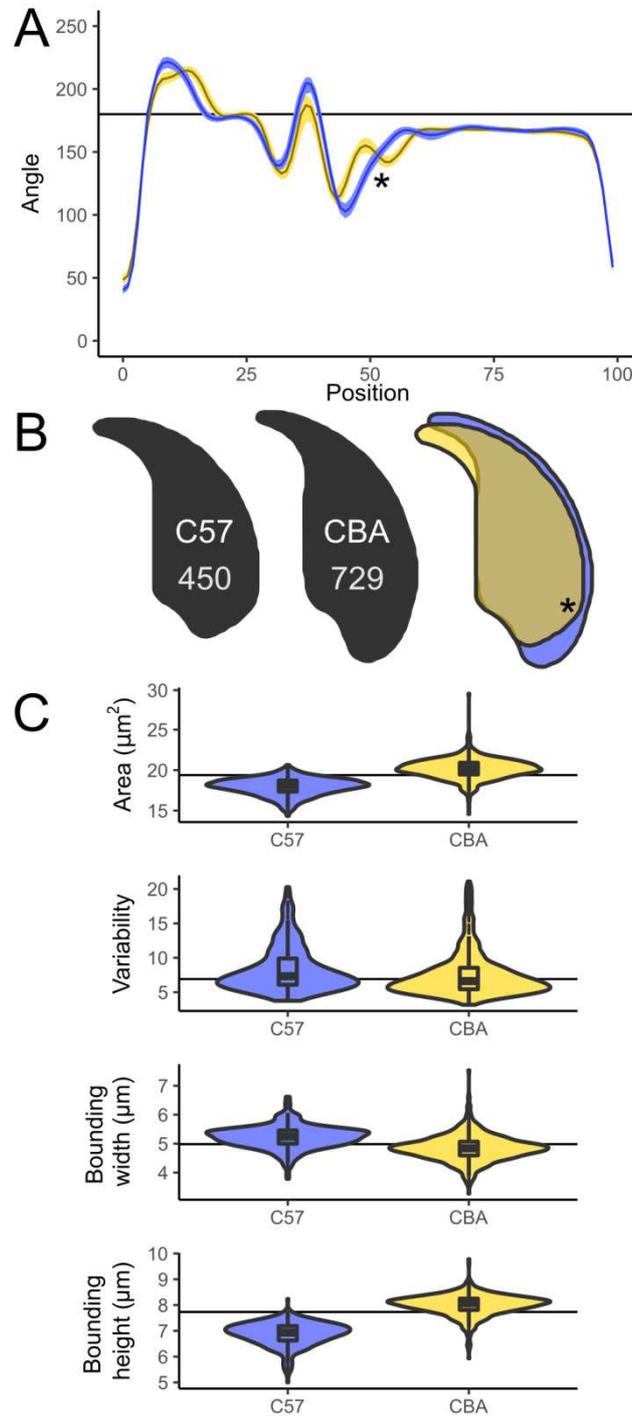

Figure 2: A) Comparison of angle profiles between C57Bl6 (yellow) and CBA (blue),
showing the median and interquartile range of the nuclear angle profiles. B) Consensus
nuclei from each population, and the overlap showing the regions differing. C) Size and
shape measurements between the strains; sperm numbers are shown on the consensus
nuclei. The prominent dorsal angle in C57Bl6 nuclei is marked with an asterisk.

274

275 CBA and C57Bl6 have previously been characterised by Wyrobek et al [20], who measured
276 160 nuclei of each genotype by manual tracing of projected microscope images of eosin-
277 stained sperm heads. We found our measured values to be similar (Supplementary Table 6)
278 but slightly smaller - as expected given that their measurements are for the entire sperm
279 head rather than just the nucleus. We measured the CBAs to be 12% longer than the
280 C57Bl6s, again close to the previously published 13.5%.

281

282 *The degree of intra-sample morphological variability is affected both by inbreeding*

283 *and inter-species hybridisation*

284

285 Having demonstrated the software can distinguish differences between two genotypes, we

286 carried out a preliminary investigation of the extent to which sperm shape variability in

287 classical laboratory strains is affected by two factors: inbreeding and the complex inter-

288 subspecific mosaic origin of these strains. To do this, we compared a panel of inbred

289 laboratory strains to (a) outbred laboratory strains, and (b) wild-derived inbred strains (Table

290 1). Biological replicate samples from the inbred strains represent either single animals

291 (laboratory inbred strains) or a pool of two animals (wild-derived inbred strains). For the

292 outbred strains, several individuals were pooled to sample the diversity across the

293 population. A comparison of the average nuclear shape for each strain is shown in Figure 3.

294 In addition to each strain having a characteristic sperm morphology, different strains showed

295 different levels of intra-sample variability. Importantly, breakdown by biological replicates

296 shows that these data reflect true strain differences rather than sample-specific factors such

297 as technical differences between imaging sessions or choice of fixative (Supplementary

298 Figure 12; Supplementary Table 2).

299
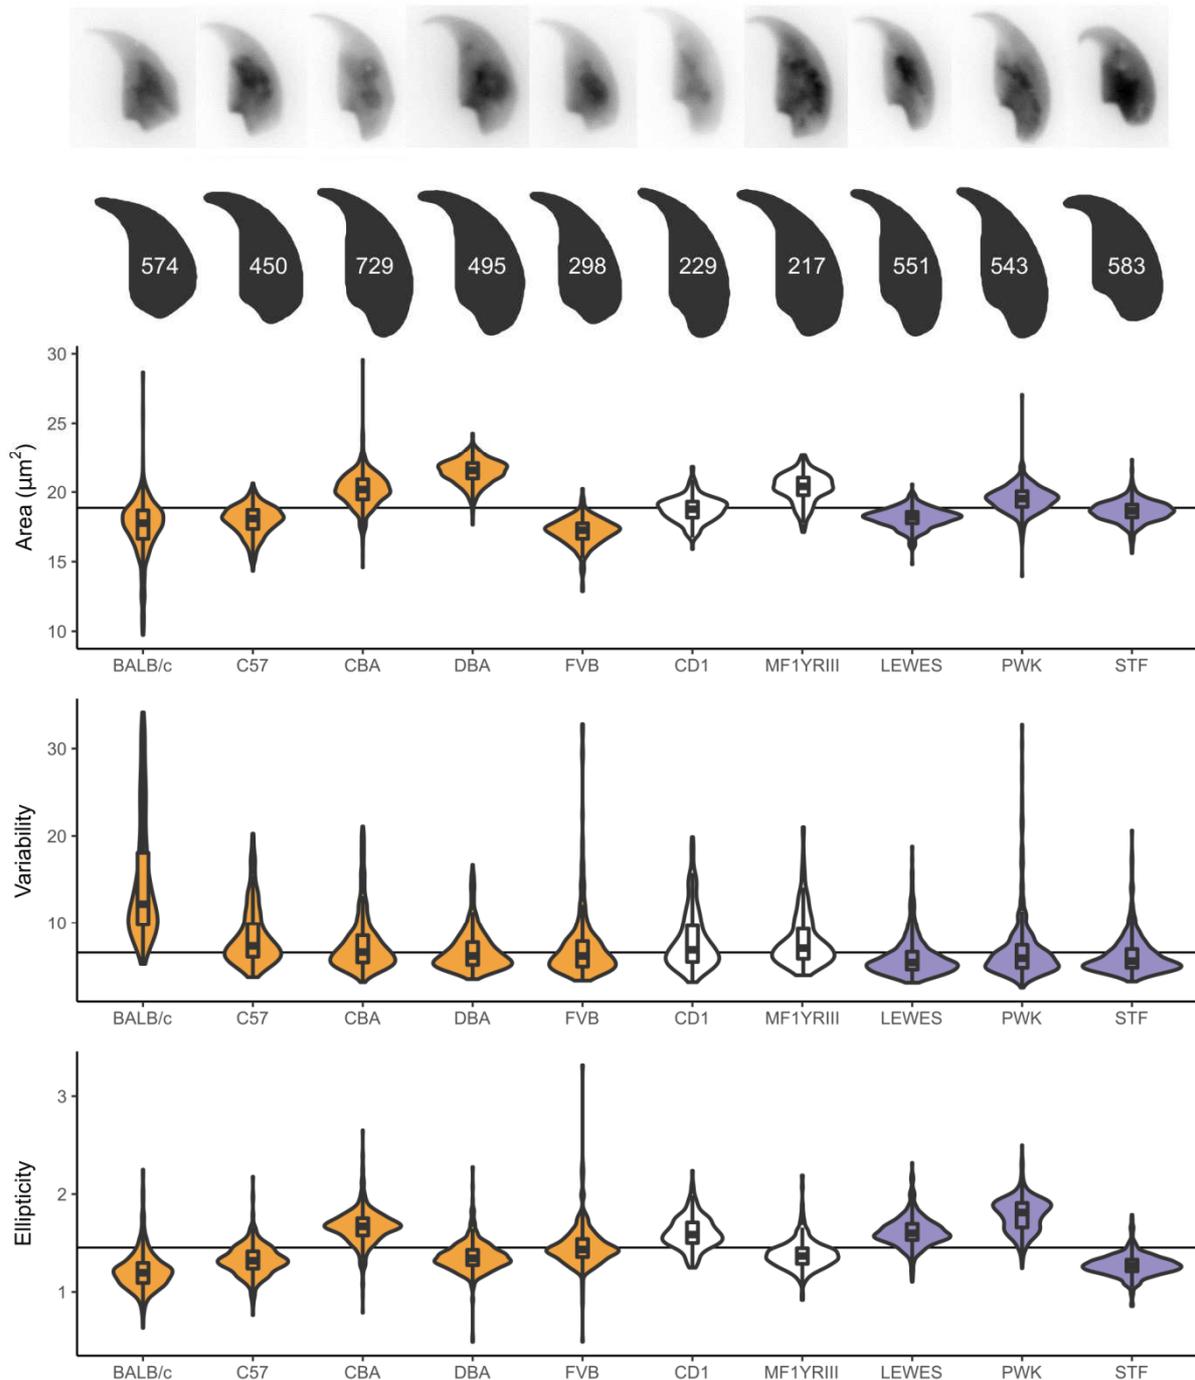

Figure 3: Parameters for additional strains examined, with representative nuclei and population consensus nucleus showing the number of analysed sperm. Samples are colored according to their type: from left to right: inbred (yellow), outbred (white) and inbred wild-derived (blue).

Some of the automatically identified landmarks were consistently found across all strains, such as the tip of the apical hook and the point of maximum curvature at the base of the sperm head, while others (such as the dorsal angle and the indentation at the tail attachment

309 site) were variable between strains. Of all the strains studied, only five showed a clear dorsal

310 angle, with the others having a smoother profile posterior to the acrosome. The distance

311 from the rear reference point to the dorsal angle was characteristic for each of these five

312 strains, as was the variability in this measurement, with BALB/c mice showing highest

313 variability. Supplementary Figure 13 demonstrates the ubiquitous and variable landmarks

314 discovered by the segmentation analysis and shows the detailed segmentation pattern for

315 each strain, while Supplementary Table 3 gives the numerical segment length data for each

316 strain.

317

318 Overall sperm shape variability within each strain was assessed using a new measure based

319 on the similarity of each cell's angle profile to the median for that strain. This correlated well

320 with other population measures of variability such as the coefficients of variation for area,

321 bounding height and perimeter (Supplementary

322 Table 7). The BALB/c mice have the most variable shape profiles of all the strains we

323 analysed, as well as the highest coefficient of variability in area, height and width (Figure 3).

324 The other inbred laboratory strains all showed low intra-strain variability despite the fact that

325 there were marked differences in sperm size and shape between strains. Of the inbred

326 laboratory strains tested, CBA and DBA had the lowest intra-sample variability. The two

327 outbred strains, CD1 and MF1Y[RIII] both showed slightly higher intra-sample variability. This

328 may reflect the fact that these samples were pooled samples derived from multiple

329 genetically unique individuals. Of the wild-derived strains, all three lineages analysed (*M. m.*

330 *domesticus*, *M. m. musculus* and *M. spretus*) had lower variability than any of the standard

331 laboratory strains, despite that fact that these wild-derived strains are inbred.

332

333 *C57Bl6 / CBA F1 strain cross males demonstrate the effects of each parental*

334 *genotype on sperm shape and stabilisation of sperm morphology in F1 males*

335

336 We investigated the impact of strain background and genetic interactions using one specific

337 reciprocal cross, between C57Bl6 and CBAs. The use of F1 animals means the resulting

338 animals are no longer inbred, but still yields a uniform population of genetically identical

339 males from each cross. B6CBA mice are the F1 offspring of a female B6 with a male CBA

340 and CBAB6 mice are the reciprocal cross. Sperm morphology for both directions of the cross

341 matches the CBA parental strain closely, indicating a dominant effect of the CBA genotype

342 (Figure 4A), and both types of F1 sperm are much more similar to the CBA parent in cross

343 sectional area (Figure 4B). Consistent with previous work [34], F1 males showed less

344 variability in their sperm shape compared to either parent strain, suggesting that inbreeding

345 acts to destabilise sperm morphology, and this is relieved via heterosis in the F1s.

346

347

348
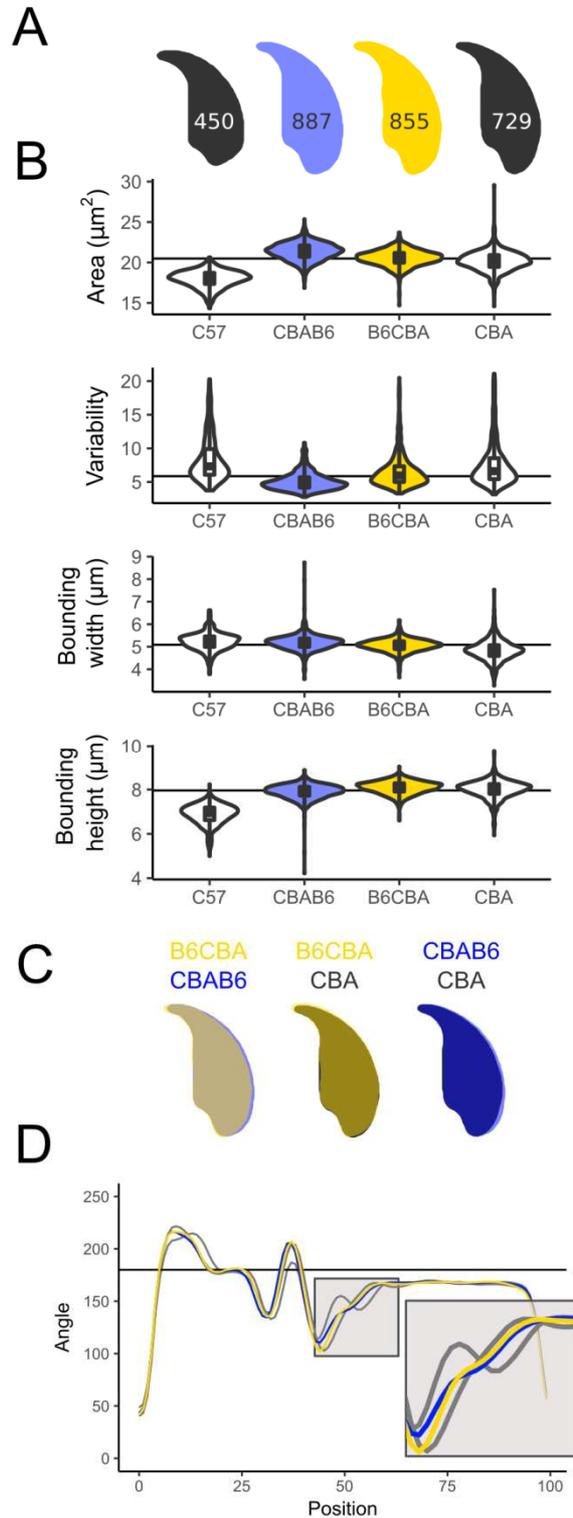

Figure 4: Subtle differences can be seen between a CBAB6 (CBA mother; blue) and a
B6CBA (C57Bl6 mother; yellow). Both are intermediate to the parental shapes (grey), but
CBAB6 sperm are wider, and their shape is closer to that of the C57Bl6. A) Consensus
nuclei with the number of analysed sperm; B) Size measurements; C) Overlay of consensus
nuclei; D) comparison of angle profiles; the tail attachment region is expanded in the inset.

354

355   The reciprocal cross data allows us to look for parent-of-origin effects on sperm shape. We

356   found two differences, in sperm cross-sectional area and in bounding width. CBAB6s have a

357   slightly larger sperm area than the B6CBAs (19.3µm^2 versus 18.6µm^2, p<0.001) and the

358   region around the posterior of the nucleus is widened in the CBAB6s, intermediate to CBA

359   and C57Bl6 (Figure 4B/C). The differences around the posterior are largely driven by

360   changes in the dorsal angle, which is present in C57, absent in CBA, and virtually absent in

361   both reciprocal F1 cross males (Figure 4D). For bounding width, we find that this parameter

362   is influenced by the male parent: CBAB6 and B6CBA are significantly different to each other

363   (p=0.0016), as are C57Bl6 and CBA (p=1.27E-12), but there is no significant difference

364   between C57Bl6 and CBAB6 (p=0.18) or between CBA and B6CBA (p=0.095). This

365   suggests that this aspect of sperm shape may be influenced either by sex chromosome or

366   mitochondrial background or by autosomal imprinted loci.

367

368

369   *Hierarchical clustering can separate samples based on shape differences*

370

371   Finally, we investigated the use of unsupervised cluster analysis of sperm shape parameters

372   to detect different morphological sub-populations within a single sample. Using a hierarchical

373   clusterer, we separated sperm based on their shape profiles. Initial testing using data from

374   C57Bl6 and CBA males showed that the clusterer performed at least as well (96% accuracy)

375   as experienced assessors (97% accuracy), and substantially better than novice assessors

376   (75% accuracy) at distinguishing between these two strains (Supplementary Table 4 and

377   Supplementary figure 14).

378

379   Next, we looked at using the clustering for novel shape discovery in BALB/c, the strain with

380   highest within-sample variability. Clustering revealed four major groups of sperm shape,

381   from mostly normal sperm through to severely shrunken and misshapen sperm (Figure 5).

382 Each of the two BALB/c samples was equally represented in the clusters (Supplementary

383 table S7), i.e. the clustering procedure can categorise intra-strain morphological variability

384 independent of any individual biological or technical variation between the samples. The final

385 class is still highly variable compared to the other classes; sub-clustering these nuclei further

386 reveals a separation into two groups of highly abnormal sperm (Supplementary figure 15) as

387 previously described [32]. While the most normal sperm had near-normal placement of the

388 dorsal angle, and a normal tail attachment site, the most heavily distorted sperm showed

389 frequent presence of additional sharp angles in the sperm outline, effacement of the tail

390 attachment site due to compression of the rear of the sperm head, and an ever more

391 prominent and misplaced dorsal angle that may reflect altered microtubule dynamics during

392 nuclear shaping.

393

394
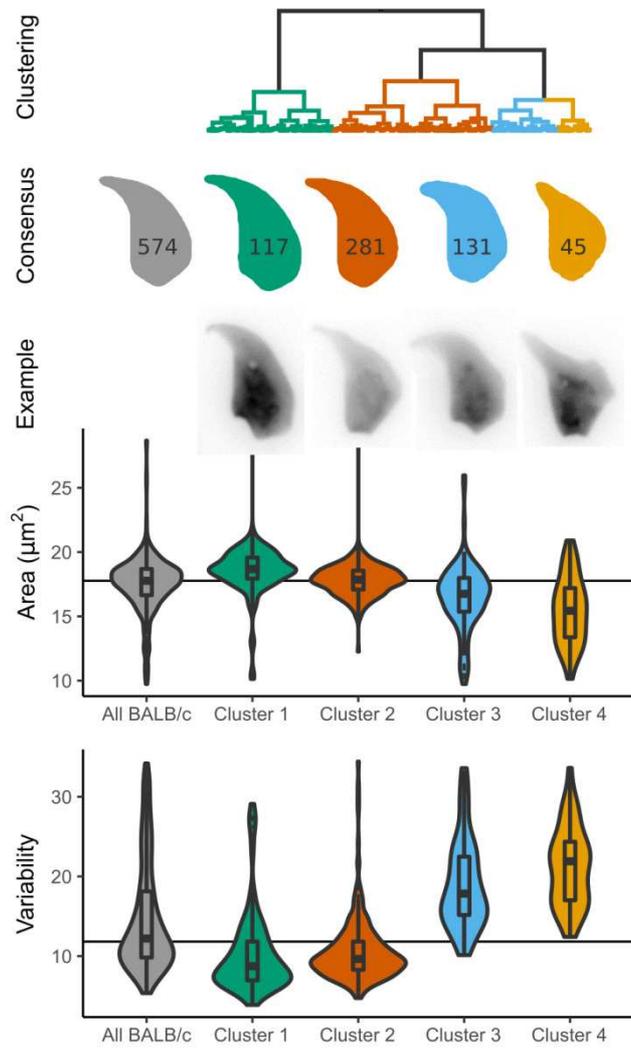

Figure 5: Clustering of BALB/c sperm reveals sub-populations of nuclei. Compared to the overall population of BALB/c sperm (grey), nuclei with distinct shapes are revealed, from mostly normal (green) to highly abnormal (yellow). The number of sperm in each cluster are given on the consensus shape. Sperm from each of the two animals are equally represented in each cluster (Supplementary Table S7).

400

Discussion

We present a novel tool for nuclear morphometry, which quantitatively measures a range of nuclear and sub-nuclear size and shape parameters. While we have chosen mouse sperm to demonstrate the software, the analysis steps will work on many symmetric or asymmetric shapes of nuclei including, but not limited to sperm from other species (e.g. [35]).

At the object detection stage, we use an edge detection algorithm that is markedly more effective than fixed-threshold detection. At the shape decomposition step, we introduce a modification of the Zahn-Roskies transform [32] that sensitively detects the various angular landmarks around the nuclear periphery without the need for manual intervention. Together, these key innovations permit automation of the steps involved in object detection, shape decomposition and comparison, massively increasing the number of nuclei that can be quantified and compared to each other. This allows the use of sample numbers that accurately capture not only fixed size and shape differences between samples, but also the detection and classification of intra-sample variability; with a total of 8,749 nuclei being measured during this preliminary study.

Comparison of sperm shape and variability within and between strains

Our observations support previous studies of mouse sperm morphological variation (e.g. [4,20]), and add further information on the precise regions of the sperm head that that differ between strains. We also demonstrate the variability of sperm morphology within each given strain. In particular, we examined the presence and placement of the dorsal angle of the sperm. This feature is created by pressure from the manchette: a cone-shaped array of microtubules that forms behind the nucleus and slides backwards during spermiogenesis,

427   shaping the rear of the sperm head in the process. Defects in katanin p80, a microtubule

428   severing protein, lead to failure of this process and abnormal compression of the base of the

429   sperm head [6]. The narrowing of the tail attachment site seen in FVB and BALB/c males,

430   together with the prominent dorsal angle seen in both strains (especially the latter) may

431   indicate that manchette migration is altered in these males.

432

433   The greatest sperm shape variability was observed in the BALB/c animals, a strain with poor

434   sperm morphology and high levels of sperm aneuploidy. Kishikawa et al [36] observed

435   different classes of sperm head shape, which we were able to recapitulate. In their analysis,

436   the authors found chromosomal abnormalities in 35% of sperm that were scored as highly

437   abnormal according to their criteria, but also in 15% of sperm that were scored as

438   morphologically normal. Given that our new analysis detects classes with more subtle shape

439   differences, we hypothesise that these new classes may also be enriched for chromosomal

440   defects. Further differences await characterisation: different classes of sperm morphology

441   have been described depending on the particular substrain and age of the animal [37].

442

443

444   *Investigating the origin of elevated within-sample variability in laboratory strains*

445

446   Consistent with [34], we found that an F1 cross between C57Bl6 and CBA laboratory strains

447   lowered sperm shape variability (see below), suggesting that the parental inbred strains

448   have fixed combinations of alleles that lead to less stable sperm morphology. However, the

449   least variable strains we examined were the wild-derived inbred strains PWK, LEW and STF,

450   representing *M. m. musculus*, *M.m. domesticus* and *M. spretus* respectively. Since these

451   three strains are also inbred, this suggests that the variety of sperm shapes in laboratory

452   strains, and the elevated level of intra-individual variability in all the laboratory strains is not

453   solely a consequence of inbreeding.

454

455 Instead, this is potentially linked to the status of the laboratory mouse as a hybrid between

456 several mouse subspecies – a factor that may have disrupted regulatory interactions

457 throughout the genome, particularly interactions involving the sex chromosomes [38–40].

458 Against this, PWK, despite being predominantly of *musculus* origin, nevertheless has

459 substantial introgression of *domesticus* DNA, of the order of ~6-7% of the genome [40,41].

460 The degree of disruption may therefore depend on both the direction of introgression and the

461 specific regions involved, and the various different classical and wild-derived inbred strains

462 may have fixed different combinations of incompatible alleles that collectively destabilise

463 sperm development to varying extents in each strain [41].

464

465 An alternative but not mutually exclusive explanation for the difference between classical

466 laboratory inbred strains and wild-derived inbred strains is that the classical strains have

467 been selected over multiple generations for their ability to breed well in captivity – indeed

468 FVB is particularly known for its fecundity [42]. Under laboratory conditions of non-

469 competitive mating, co-housing a single male with one or more females, it is likely that

470 reproductive output is driven largely by maternal factors. In strains experimentally selected

471 for high fecundity, male fertility and sperm morphology/motility parameters are compromised,

472 suggestive of a trade-off between the male and female factors necessary for high fecundity

473 in a laboratory environment [43].

474

475

476 *Future uses for our approach in speciation, fertility, and toxicology studies*

477

478

479 Sperm morphology is of interest from an evolutionary perspective; sperm are under intense

480 selection, sperm morphology has been found to be an important criterion influencing male

481   fertility in many species [44]. Altered sperm head morphology has emerged as a common

482   form of hybrid male sterility in mice [11–14,45]. Some sterility factors broadly impair

483   spermatogenesis, resulting in reduced sperm counts and lower motility in addition to head

484   shape alterations. However, several studies have now shown that hybrid sterility Quantitative

485   Trait Loci (QTL) in mice often correspond to specific reproductive phenotypes [14]. The

486   challenges of manually quantifying morphology in large mapping panels has necessitated

487   the use of crude categorical scores [11,13,45], hampering quantitative precision and limiting

488   the ability to draw causal links between hybrid incompatibilities and specific aspects of

489   sperm morphological development. Our approach assists firstly by enabling more rigorous

490   quantitation of sperm shape, and secondly by enabling the large sample sizes and

491   systematic approach needed for mapping studies.

492

493   Fertility rate and IVF efficiency has been correlated with the genetic background of sperm

494   among inbred mouse strains [46]. Furthermore, many studies have shown that the genetic

495   background of a strain can influence sperm morphology. For example, deletion of the long

496   arm of the Y chromosome results in a more severe phenotype on B10.BR background than

497   on CBA [47]. Mashiko et al [27] have suggested morphology of sperm is associated with

498   fertilising efficiency in at least two mouse strains (B6D2F1 and C57Bl6/N). Since particular

499   genetic mutations in mouse sperm shape are associated with characteristic nuclear shape

500   alterations (e.g. [15]), detailed examination of sperm from natural mutant and/or targeted

501   knockout animals may point to pathways of interest for understanding spermiogenesis and

502   male fertility more generally.

503

504   In toxicological analysis, rodent sperm are conventionally manually classified into classes of

505   predefined morphological abnormality (e.g. [16,48]). The hierarchical clustering implemented

506   within the software is able to separate nuclei based on shape as accurately as an

507   experienced manual sperm scorer; and is faster and more consistent. This may be of use in

508   samples where the nature and degree of abnormalities is hard for humans to reliably

509   quantify – e.g. where the shape defects seen do not match existing scoring charts. The fact

510   that specific genetic lesions cause specific shape changes means that the sperm shape

511   might in principle give information not just about the presence/absence of toxicity but also its

512   mode of action. Our new analysis approach will complement existing studies of sperm

513   function, which, in clinical settings or in automated CASA platforms (e.g. [49]), is still lacking

514   detailed morphological data [21].

568

569

570   **Table 2: Parameters measured in the software**

571

Parameter	Description
Area	A; the two dimensional area of the nucleus
Perimeter	P; the length of the nuclear perimeter
Max feret diameter	the maximum caliper diameter across the nucleus
Min diameter	the shortest caliper diameter through the centre of mass of the nucleus
Variability	$\sqrt{((\sum(d^2))/L)}$; the square root of the sum-of-squares difference (d) at each index between between the nuclear profile and the dataset median profile, after normalisation to a fixed length (L)
Ellipticity	H/W; the height (H) divided by width (W) of the nuclear bounding box when the nucleus is vertically oriented
Circularity	$4\pi A/P^2$; the closeness of the nucleus to a circle, between 0 and 1, where 1 is a perfect circle.
Bounding width	W; the width of the bounding rectangle of the vertically oriented nucleus
Bounding height	H; the height of the bounding rectangle of the vertically oriented nucleus
Angle between reference points	the angle between the tip, the centre of mass, and the caudal reference point (defined as the point of greatest curvature at the rear of the sperm head)
Length of hook [rodent sperm only]	the distance from the vertical alignment region to the x-edge of the bounding rectangle on the hook side (Figure 1D)
Width of body [rodent sperm only]	the distance from the vertical region to the x-edge of the bounding rectangle on the body side (Figure 1D)
Segment lengths	the length of each segment along the perimeter of the nucleus

572
