Abstract

**Background:** Although high-density lipoprotein (HDL) and non-HDL cholesterol have opposite associations with coronary heart disease (CHD), multi-country reports of lipid trends only use total cholesterol (TC). Our aim was to compare trends in total, HDL and non-HDL cholesterol and total-to-HDL cholesterol ratio in Asian and Western countries.

**Methods:** We pooled 458 population-based studies with 82.1 million participants in 23 Asian and Western countries. We estimated changes in mean total, HDL and non-HDL cholesterol, and mean total-to-HDL cholesterol ratio by country, sex and age group.

**Results:** Since ~1980, mean TC increased in Asian countries. In Japan and South Korea, TC rise was due to rising HDL cholesterol, which increased by up to 0.17 mmol/L per decade in Japanese women; in China, it was due to rising non-HDL cholesterol. TC declined in Western countries, except in Polish men. The decline was largest in Finland and Norway, ~0.4 mmol/L per decade. The decline in TC in most Western countries was the net effect of an increase in HDL cholesterol and a decline in non-HDL cholesterol, with the HDL cholesterol increase largest in New Zealand and Switzerland. Mean total-to-HDL cholesterol ratio declined in Japan, South Korea and most Western countries, by as much as ~0.7 per decade in Swiss men (equivalent to ~26% decline in CHD risk per decade). The ratio increased in China.

**Conclusions:** HDL cholesterol has risen and total-to-HDL cholesterol ratio has declined in many Western countries, Japan and South Korea, with only weak correlation to changes in TC or non-HDL cholesterol.
Keywords: total cholesterol, LDL cholesterol, HDL cholesterol, blood lipids, multi-country study.
Introduction

Blood cholesterol is one of the most important risk factors for coronary heart disease (CHD) (1-4). Population-level data on blood cholesterol are an important input for planning and evaluating the impacts of public health interventions and treatment programmes on entire countries and communities. Comparable data in different countries can help to benchmark success in lowering cholesterol across countries, and to understand reasons behind differential trends, both those that were implemented as active interventions and unplanned secular changes in nutrition and health behaviours.

Multi-country reporting of lipid trends has so far been based on total cholesterol (TC) (5, 6). However, high-density lipoprotein (HDL) and non-HDL or low-density lipoprotein (LDL) cholesterol have opposite associations with coronary heart disease (CHD) (1, 2), and can respond differently to changes in diet and treatment. Currently, there are no comparable cross-country data on lipid fractions, including LDL and HDL cholesterol, and total-to-HDL cholesterol ratio; only studies in individual countries have reported such trends (7-27). To fill this important gap, we used population-based data to analyse and compare long-term changes in TC, HDL and non-HDL cholesterol, and total-to-HDL cholesterol ratio in Western and Asian countries over a period of more than 30 years.

Methods

Primary outcomes

For this analysis we used mean total, HDL and non-HDL cholesterol and mean total-to-HDL cholesterol ratio as primary outcomes. The hazardous effects of blood cholesterol on CHD was first established in the Framingham Study, focusing on TC (28). However, physiological studies (29) and subsequent analyses of the Framingham Study (30) found that the fractions of
blood cholesterol carried by different lipoproteins and ratios affect CHD risk differentially, and at times in opposite directions. Pooled analyses of observational epidemiological studies have established that CHD risk is associated directly with LDL and non-HDL cholesterol, and inversely with HDL cholesterol (1, 2). As a result lipid ratios such as total-to-HDL cholesterol ratio, which incorporates information on lipid fractions with opposite associations, have emerged as a particularly good predictor of CHD risk in clinical and epidemiological applications (1, 2). Randomised clinical trials have also shown that lowering LDL and non-HDL cholesterol lowers CHD risk (31-34). In contrast, the results of observational studies on HDL cholesterol have not been replicated in randomised trials nor in Mendelian randomisation studies (35-38).

We used non-HDL cholesterol rather than LDL cholesterol because most studies in our analysis had measured TC and HDL cholesterol, from which non-HDL cholesterol can be calculated by subtraction. In contrast, LDL cholesterol was directly measured in 13% of studies. When LDL cholesterol is not directly measured, its estimation requires data on triglycerides, which were available in only 61% of studies. Further, the most commonly used estimation method, i.e. the Friedewald equation, can be inaccurate (39). We found that non-HDL and LDL cholesterol were correlated in studies with data on both variables (r =0.93) (Supplementary Figure 1). Non-HDL cholesterol predicts CHD risk at least as well as LDL cholesterol (40, 41), because it includes cholesterol in LDL, lipoprotein(a), intermediate-density lipoprotein, very-low-density lipoprotein, and lipoprotein remnants, and is thus a simple measure of cholesterol content within all atherogenic lipoproteins.

Countries analysed
Our analyses included Asian and Western countries that had at least five population-based studies (or at least three if the studies were nationally representative) with measurement of total and HDL cholesterol over a period of at least 15 years from 1970 onwards, with at least one data source after 2005. Twenty one countries, listed below, met these criteria.

- Nordic countries: Finland, Iceland and Norway.
- Eastern central Europe: Czech Republic, Lithuania, Poland and Slovakia.
- Western central Europe: Belgium, Germany and Switzerland.
- Southern Europe: France, Italy and Spain.
- High-income English-speaking countries: Australia, Canada, New Zealand, UK and USA.
- East and southeast Asia: China, Japan and South Korea.

Two additional countries, Sweden and Thailand, had sufficient data on TC but not on HDL cholesterol, and were included in TC analysis only.

*Data sources*

We used studies that had measured cholesterol in representative samples of the national population or of one or more subnational regions and communities. We used a database on cardiometabolic risk factors collated by the Non-Communicable Disease Risk Factor Collaboration (NCD-RisC). NCD-RisC is a worldwide network of health researchers and practitioners whose aim is to document systematically worldwide trends and variations in NCD risk factors (42-45). The database was collated through multiple routes for identifying and accessing data. We accessed publicly available population-based measurement surveys (e.g., Demographic and Health Surveys (DHS), Global School-based Student Health Surveys (GSHS), the European Health Interview and Health Examination Surveys (EHIS and EHES) and those available via the Inter-university Consortium for Political and Social Research (ICPSR). We requested, via the World Health Organization (WHO) and its regional and
country offices, help with identification and access to population-based surveys from ministries of health and other national health and statistical agencies. Requests were also sent via the World Heart Federation to its national partners. We made similar requests to the co-authors of an earlier pooled analysis of cardiometabolic risk factors (5, 46-48), and invited them to reanalyse data from their studies and join NCD-RisC. Finally, to identify major sources not accessed through the above routes, we searched and reviewed published studies as detailed previously (42-44), and invited all eligible studies to join NCD-RisC.

Anonymised individual record data from sources included in NCD-RisC were reanalysed by the Pooled Analysis and Writing Group or by data holders according to a common protocol. Within each survey, we included participants aged 18 years and older who were not pregnant. We dropped participants with implausible cholesterol levels (defined as TC <1.75 mmol/L or TC >20 mmol/L; HDL cholesterol <0.4 mmol/L or >5 mmol/L; TC values < HDL values) (<0.1% of all subjects). To ensure summaries were prepared according to the study protocol, the Pooled Analysis and Writing Group provided computer code to NCD-RisC members who requested assistance. All submitted data were checked by at least two independent members of the Pooled Analysis and Writing Group. Questions and clarifications were discussed with NCD-RisC members and resolved before data were incorporated in the database. Finally, we incorporated all nationally representative data from sources that were identified but not accessed via the above routes, by extracting summary statistics from published reports. Data were extracted from published reports only when reported by sex and in age groups no wider than 20 years. We also used data from a previous global-data pooling study (5) when such data had not been accessed through the routes described.
All NCD-RisC members are asked periodically to review the list of sources from their country, to suggest additional sources not in the database, and to verify that the included data meet the inclusion criteria listed below and are not duplicates. The NCD-RisC database is continuously updated through this contact with NCD-RisC members and all the above routes. For this paper, we used data from the NCD-RisC database for the 23 countries included in the analysis, for years 1970 to 2018 and ages 40-79 years.

Data inclusion and exclusion

Data sources were included in the NCD-RisC database if:

• measured data on total, LDL, HDL cholesterol, or triglycerides were available;
• study participants were ten years of age or older;
• data were collected using a probabilistic sampling method with a defined sampling frame;
• data were from population samples at the national, sub-national (i.e., covering one or more sub-national regions, more than three urban communities or more than five rural communities), or community level.

We excluded all data sources that included only hypercholesterolemia or dyslipidemia diagnosis history or medication status without measurement of at least one of the above biomarkers. We also excluded data sources on population subgroups whose lipid profile may differ systematically from the general population, including:

• studies that had included or excluded people based on their health status or cardiovascular risk;
• studies whose participants were only ethnic minorities;
• specific educational, occupational, or socioeconomic subgroups, with the exception noted below; and

• those recruited through health facilities, with the exception noted below.

We used data whose sampling frame was health insurance schemes in countries where at least 80% of the population were insured. Finally, we used data collected through general practice and primary care systems in high-income and central European countries with universal insurance, because contact with the primary care systems tends to be as good as or better than response rates for population-based surveys.

We used data sources regardless of fasting status, because the differences between fasting and non-fasting measurements are negligible for our primary outcomes (49). From the CDC-NHLBI Lipid Standardization Program in the 1950s, there has been an understanding of the need for, and systematic efforts to achieve, standardisation of lipid measurements. The difference between any standardised method and the CDC Reference method should be less than 3% for TC and less than 5% for HDL cholesterol (less than 10% before the mid-1990s) (50). More than three quarters of the studies in our analysis participated in a lipid standardisation programme (Supplementary Table 1 and Supplementary Figure 2). A summary of data available by country is shown in Supplementary Table 2 and characteristics of each study are shown in Supplementary Table 1.

We extracted data for ages 40-79 years, because people aged below 40 years have a lower cardiovascular risk and because data in older ages were available in fewer surveys. CHD mortality increases with age while hazard ratios for the effects of cholesterol on CHD decrease with age (1, 2). As a result, a larger share of CHD deaths are attributable to elevated cholesterol
in middle-aged ages, but the number of cholesterol-attributable deaths continues to increase with age (4). We present results for 40-59 years as the primary analysis, because data on these age groups were available for all countries included in the analysis. To investigate the role of age in our findings, we compared results for ages 40-59 years to those of 60-79 years in countries with data for the entire age range of 40-79 years.

**Statistical methods**

For each study, we calculated mean total, HDL and non-HDL cholesterol and mean total-to-HDL cholesterol ratio by sex and 10-year age groups. Total-to-HDL cholesterol ratio was calculated using individual records before averaging for each sex and age group. All analyses incorporated appropriate complex survey design and survey sample weights in calculating age-sex-specific means.

For each primary outcome, and for each country, sex and age group, we calculated average change over the entire period of data availability by fitting a linear regression with the study-specific means as dependent variable and year as the independent variable. Each data point was weighted by the inverse of the square of its standard error, so that larger studies had more influence on the estimated change. We multiplied the slope of the fitted line by ten to calculate average change per decade. We also used the fitted line to estimate total, HDL and non-HDL cholesterol and total-to-HDL cholesterol ratio values for a consistent period of 1980 to 2015 for all countries. For countries with data starting before 1980 and ending after 2015, this is equivalent to using the fitted line to interpolate for 1980 and 2015; for those with data starting after 1980 or ending before 2015, values for 1980 and/or 2015 were extrapolated using the fitted line. In a sensitivity analysis, we fitted a nonlinear (LOESS) regression to examine by how much our results are influenced by use of linear trend. For each primary outcome, and for
each country, results were calculated by 10-year age groups, separately for men and women, and then age-standardised into two age bands, 40-59 years and 60-79 years, by taking a weighted average of age-specific results and using weights from the WHO standard population. Analyses were performed in R version 3.4.0 (The R Foundation for Statistical Computing).

**Results**

**Data availability**

We used 438 population-based studies, collected from 1970 to 2018 in 21 countries that met our inclusion criteria for TC as well as lipid fractions. An additional 20 studies were used for analysis of TC in Thailand and Sweden. These studies included blood lipid measurements in 82.1 million participants, 79 million of whom were aged 40-79 years. The number of data sources ranged from 5 in Slovakia to 56 in Japan. The average time between first and last studies in a country was around three decades. For the primary analysis, we used 425 studies with data for ages 40-59 years. All these 425 studies had data on TC. In the 21 countries included in the analysis of lipid fractions, 368 of 405 studies (90.9%) had data on HDL cholesterol, and 367 (90.6%) on total-to-HDL cholesterol ratio. Details of data availability by country, and characteristics of each study, are shown in Supplementary Tables 1 and 2.

**Total cholesterol**

Mean TC declined in men and women aged 40-59 years in most Western countries, except in Polish men whose TC was about the same at the beginning and end of analysis period (Figure 1). The absence of long-term change in Poland was a result of a rise in mean TC until the late 1990s, followed by a decline (Supplementary Figure 3). In both sexes, the decline was larger in Nordic countries and central Europe than in English-speaking countries and southern Europe. TC decline in men ranged from <0.1 mmol/L per decade in Lithuania, New Zealand and France
to ~0.4 mmol/L per decade in Norway, Finland, and Belgium. In women, the range was from <0.1 mmol/L per decade in Poland, France, and Italy to ~0.4 mmol/L per decade in Finland, Norway and Belgium. TC increased in all three Asian countries, with the largest increase in China and Thailand, by ~0.3 mmol/L per decade. Despite this rise, Chinese women (but not men) still had the lowest estimated mean TC of all 23 countries in 2015 (5.0 mmol/L) (Supplementary Figure 4). The highest mean TCs in 2015 were those in Lithuanian and French men and Thai women, all above 5.7 mmol/L.

**HDL and non-HDL cholesterol**

Among the three Asian countries with data on lipid fractions, the rise in mean TC in Japan and South Korea was largely due to an increase in mean HDL cholesterol, which among Japanese and South Korean women was offset partly by a decline in non-HDL cholesterol (Figure 2). The rise in HDL cholesterol ranged from 0.04 mmol/L per decade in South Korean men to 0.17 mmol/L per decade in Japanese women. In contrast, in China, TC rise was due to an increase in non-HDL cholesterol while HDL cholesterol remained unchanged in women and increased slightly in men.

The decline in mean TC in many Western countries was the net effect of a decline in non-HDL cholesterol and an increase in HDL cholesterol (Figure 2). The key exceptions were men and women in Germany and Norway, and men in Czech Republic and Slovakia, where both HDL and non-HDL cholesterol declined. Similar to TC, mean non-HDL cholesterol generally declined more in Nordic countries and central Europe than in English-speaking and southern European countries. The largest rise in mean HDL cholesterol occurred in New Zealand and Switzerland, by 0.10-0.15 mmol/L per decade in the two sexes.
Change in mean HDL cholesterol and change in mean non-HDL cholesterol were not correlated ($r = -0.004$ for men and -0.07 for women) (Figure 3). In 2015, the lowest levels of mean non-HDL cholesterol were those in China and Belgium for men (3.7 mmol/L) and in Iceland for women (3.3 mmol/L) (Supplementary Figure 5). The highest were in France, 4.4 mmol/L for men and 4.0 mmol/L for women.

*Total-to-HDL cholesterol ratio*

Mean total-to-HDL cholesterol ratio declined in most Western countries, by as much as ~0.7 per decade in Swiss men and ~0.5 per decade in New Zealand and Swiss women (Figure 4). The ratio changed little in Slovakian men. In Asia, China experienced a rise in mean total-to-HDL cholesterol ratio, because of the above-mentioned non-favourable changes in both non-HDL and HDL cholesterol. In contrast, despite the rise in mean TC, total-to-HDL cholesterol ratio declined in Japan and South Korea because HDL cholesterol increased by a larger proportion than did TC.

Change in total-to-HDL cholesterol ratio was only moderately correlated with change in TC (correlation coefficient = 0.52 for men and 0.53 for women) (Figure 5). Japan and South Korea were particularly notable in having had a rise in TC but a decline in total-to-HDL cholesterol ratio, and Norway, Germany and men in Slovakia in having had declining TC with little change in total-to-HDL cholesterol ratio. In 2015, the lowest ratio was that of Japanese women (2.9) and Japanese men (3.7) (Supplementary Figure 6).

*Results for people aged 60-79 years*

Results in people aged 60-79 years were moderately to strongly correlated with those aged 40-59 years (Figure 6 and Supplementary Figure 3). In virtually all countries, mean TC, non-HDL
cholesterol and total-to-HDL cholesterol ratio declined more in these older age groups than in people aged 40-59 years. The decline advantage in older ages was particularly evident for Australia and the UK, where women and men aged 60-79 years experienced a decline in non-HDL cholesterol twice as large as those aged 40-59 years. Change in mean HDL cholesterol was larger in older ages in some countries and smaller in others, indicating that its change may be due to factors that are at least partly different from those affecting non-HDL cholesterol.

**Discussion**

By conducting a comparative analysis of changes in TC and lipid fractions and ratios, we found varying rates of decline in TC in Western countries and a rise in Asian countries, leading to an overall convergence in TC among these nations. Underlying this convergence were more heterogeneous trends in HDL and non-HDL cholesterol, with HDL cholesterol rising in more than half the countries in the analysis. The diverse trends in HDL and non-HDL cholesterol resulted in substantial cross-country variation in trends for mean total-to-HDL cholesterol ratio, with the ratio declining in most countries, but increasing in China.

Our findings on TC trends are largely consistent with prior multi- and single-country reports. Differences from previous studies – e.g., in some countries that participated in the MONICA Project (6), Poland (21) and Switzerland (24) – mostly arise because our study covered a longer period and used a larger number of data sources. Fewer studies have reported trends in lipid fractions and, to our knowledge, none has done so consistently across countries. Studies that have reported trends in lipid fractions for a period longer than 15 years (8, 11, 16, 18-20, 25-27), have found changes in non-HDL cholesterol (or in LDL cholesterol for some studies) that were consistent with our results.
The observed decline in non-HDL cholesterol in Western countries is likely to have been mostly due to changes in diet – especially the replacement of saturated with unsaturated fats and reduction in trans-fats (8, 20, 51). Statins have also been widely used in high-risk patients since the 1990s (26, 52), and may have helped lower population mean, especially in older ages. In the majority of countries in our analysis, the decline in non-HDL cholesterol started in the 1980s, before statins were widely used. Further, we observed a decline in non-HDL cholesterol in men and women aged 40-49 years, among whom statin use is relatively low. Nonetheless, the higher use of statins in older ages may at least partly explain the larger decline in non-HDL observed in those aged 60-79 years (26, 53).

Changes in Western countries contrast with the substantial rise in consumption of animal fats in China (54), where statin use also remains low (55). Focusing on non-HDL cholesterol alone, however, conceals important changes in HDL cholesterol and the total-to-HDL cholesterol ratio. Although HDL cholesterol does not have a single dominant non-genetic determinant, it is affected adversely (i.e. is lower) by adiposity, type 2 diabetes, intake of trans-fats and carbohydrates, especially those with a high glycaemic index, smoking, and the use of some drugs (e.g., β-blockers, anabolic steroids) (56-63). Conversely, increases in physical activity, alcohol consumption, total fat intake, and oestrogens increase HDL cholesterol (56, 57, 59-63). A decrease in carbohydrate intake, and an increase in fat intake, may have contributed to the increase in HDL cholesterol in Japan (64, 65), South Korea (62, 66) and Switzerland (67), while declines in carbohydrate intake and smoking may have contributed to the rise in the USA (26) and some other countries. By contrast, an increase in carbohydrate intake (67) and a decline in alcohol consumption (68) have been observed in Germany, where we observed a slight decline in HDL cholesterol. The decline in smoking in most Western countries may have also contributed to the observed increase in HDL cholesterol.
The strengths of our study include its novel scope of comparing lipid fractions across countries, and using a large number of high-quality population-based studies over more than three decades. Such comprehensive data allowed us to document a significant rise in HDL cholesterol, which is considered difficult to change, in a number of Western and Asian countries as a contributor to the decline in total-to-HDL cholesterol ratio. A multi-country study, such as ours, is also affected by some limitations. Clinical trials of drugs that raise HDL cholesterol and genetic and epidemiologic studies have shown the complexity of the relationship between HDL cholesterol, HDL particles and cardiovascular and other diseases (35, 37, 38, 69). We used HDL and non-HDL cholesterol because there was significantly more data available than on LDL cholesterol and because total-to-HDL cholesterol ratio is commonly used in clinical practice. We did not analyse trends in different HDL particles because this information is not available in most population-based health surveys and because it is not commonly used to make clinical decisions. We also did not analyse emerging lipid markers such as apolipoprotein B and apolipoprotein A-I, because they are neither commonly measured in population-based health surveys, nor routinely used in clinical practice (56, 70).

We used average change per decade, estimated in a linear model, which has the advantage of being parsimonious, but trends in some countries may be non-linear. When we fitted a nonlinear LOESS regression (Supplementary Figure 3), the estimated average decadal change was similar to the estimates from the linear model in most countries. Almost 80% of the studies in our analysis had used enzymatic methods for measuring TC, which have been well standardised since at least the 1980s. Although methods to measure HDL cholesterol have evolved over time – chemical precipitation methods to separate HDL and, more recently, homogeneous assays (71) – more than three quarters of the studies in our analysis participated in a lipid standardisation programme (Supplementary Figure 2). A rise in HDL cholesterol was
also seen in countries and over periods where measurement methods did not change. Nonetheless, the observed changes in HDL cholesterol in some countries were in the same order of magnitude to which laboratories’ accuracies can be standardised. Although most studies had measured cholesterol in serum, ~11% had used plasma. Adjusting for plasma-serum differences had little impact on our results and did not change our conclusions (Supplementary Figure 7), because cholesterol measured in plasma and serum differ by only about 3% (50). Finally, although all our data were from samples of the general population, 40% came from community-based studies. In some countries, community-based studies came from the same community in different years; in others, studies were from different parts of the same country which led to additional variability in data and uncertainty in the estimated change. Our key findings on lipid fractions were also seen where the data sources covered the entire country or large parts of it. In eleven countries, our analysis was limited to ages 40-59 years because fewer studies had data in people older than 60 years of age, for whom non-HDL cholesterol may have declined more due to the use of statins, as indicated by the results in the ten countries with data covering ages 40-79 years.

While early epidemiological studies used TC as a marker of cardiovascular risk in individuals and populations (72), our study shows that the populations of Asian and Western countries have experienced large and heterogenous changes in lipid fractions, including substantial increases in HDL cholesterol and substantial falls in non-HDL cholesterol. In the best-performing countries, those in Europe and New Zealand, total-to-HDL cholesterol ratio has declined by 1.5-2.3 since the 1980s, which is equivalent to a 48-63% reduction in the risk of coronary heart disease (1). In Japan and South Korea, total-to-HDL cholesterol ratio has declined, which provides a simple explanation for the apparent paradox of declining CHD while TC increased (73). A key implication of our findings is the need for national surveillance
systems that, consistent with modern clinical practice, measure relevant lipid fractions and their determinants, including diet, health behaviours such as smoking and alcohol use, and use of statins to support the design and evaluation of public health programmes.

Despite the improvements that we have documented, the populations of all countries analysed here would benefit from lower non-HDL cholesterol and total-to-HDL cholesterol ratios. In China, which had some of the lowest recorded non-HDL cholesterol and TC levels a few decades ago, changes in diet and relatively low treatment coverage have led to unfavourable trends in lipid profiles. Therefore, population-based policies and targeted interventions to improve nutrition and enhance treatment are still needed in all these countries, and should be designed and evaluated based on their impacts on all health-relevant lipid fractions and on the corresponding health outcomes.
Key messages

- Total cholesterol (TC) has increased in Asian countries. In Japan and South Korea, TC rise was largely due to an increase in HDL cholesterol; in China, it was due to a rise in non-HDL cholesterol.

- The observed decline in TC in most Western countries was the net effect of an increase in HDL cholesterol and a decline in non-HDL cholesterol.

- Total-to-HDL cholesterol ratio has declined in many Western countries, Japan and South Korea, with only weak correlation to changes in TC or non-HDL cholesterol.

- Countries’ comparative performance in reducing the risks associated with blood cholesterol is only partially captured by trends in total cholesterol.
