29 **Abstract**

30 Changes in first metatarsal (MT1) morphology within the hominin clade are crucial for
31 reconstructing the evolution of a forefoot adapted for human-like gait. Studies of the external
32 morphology of the MT1 in humans, non-human apes and fossil hominins, have documented changes
33 in its robusticity, epiphyseal shape and its articulation with the medial cuneiform. Here, we test
34 whether trabecular structure in the MT1 reflects different loading patterns in the forefoot across extant
35 large apes and humans, and within this comparative context, infer locomotor behaviour in two fossil
36 hominins from Swartkrans, South Africa. Microtomographic scans were collected from the MT1 of
37 Pongo sp. (n=6), Gorilla gorilla (n=10), Pan troglodytes (n=10), Homo sapiens (n=11), as well as
38 SKX 5017 (*Paranthropus robustus*), and SK 1813 (Hominin gen. sp. indet.). Trabecular structure was
39 quantified within the head and base using a ‘whole-epiphysis’ approach with medtool 4.2. We found
40 that modern humans displayed relatively higher bone volume fraction (BV/TV) in the dorsal region of
41 each epiphysis and a higher overall degree of anisotropy (DA), whereas great apes showed higher
42 BV/TV in the plantar regions, reflecting dorsiflexion at the metatarsophalangeal (MTP) joint in the
43 former and plantarflexion in the latter. Both fossils displayed low DA, with SKX 5017 showing a
44 hyper-dorsal concentration of trabecular bone in the head (similar to humans), while SK 1813 showed
45 a more central trabecular distribution not seen in either humans or non-human apes. Additionally, we
46 found differences between non-human apes, modern humans, and the fossil taxa in trabecular spacing
47 (Tb.Sp.), number (Tb.N.), and thickness (Tb.th.). While low DA in both fossils suggests increased
48 mobility of the MT1, differences in their trabecular distributions could indicate variable locomotion in
49 these Pleistocene hominins (recognizing that the juvenile status of SK 1813 is a potential confounding
50 factor). In particular, evidence for consistent loading in hyper-dorsiflexion in SKX 5017 would
51 suggest locomotor behaviours beyond human-like toe off during terrestrial locomotion.

54

55

56 **1. Introduction¹**

57 One of the central questions within the study of human evolution is how and when obligate
58 bipedalism emerged. The forefoot is of particular importance in addressing this question because it
59 directly reflects the extent to which a species uses its feet for locomotion (either arboreal or terrestrial)
60 and/or manipulation. The first metatarsal (MT1) has undergone a dramatic transformation, from a
61 digit used primarily for grasping, to a digit used mainly for weight-bearing, stabilization, and
62 propulsion in modern humans (Morton, 1922; Elftman and Manter, 1935; Susman, 1983; Harcourt-
63 Smith and Aiello, 2004). Analysis of the partially preserved OH 8 foot formed a critical aspect of the
64 initial diagnosis of bipedalism in *Homo habilis* (Day and Napier, 1964; Kidd et al., 1996) and a
65 number of studies have incorporated analyses of forefoot bones to argue for committed terrestrial
66 bipedalism in *Australopithecus afarensis* (Latimer and Lovejoy, 1990; ; Ward 2002 Ward et al., 2011)
67 and an opposable hallux in *Ardipithecus ramidus* (Lovejoy et al., 2009; White et al., 2015). Equally
68 intriguing is the recent discovery of the Burtele foot, which is similar in age to *A. afarensis* but
69 displays a number of characteristics that differentiate it morphologically and suggest two different
70 types of bipedal foot loading in the hominin clade at the same time (Haile-Selassie et al., 2012). This
71 variation in hominin foot bone morphology highlights the importance of understanding the
72 form/function relationship of the MT1 in extant and fossil hominoids and, in particular, whether
73 internal bone structure can provide insights into biomechanical loads experienced by the foot during
74 different types of locomotion. Using a comparative sample of modern humans and non-human apes,
75 this study will address whether trabecular structure within the MT1 is reflective of locomotor mode.
76 Furthermore, we will compare them to fossil hominins from Swartkrans (SKX 5017 and SK 1813) to
77 test hypotheses about hominin locomotion in the Plio-Pleistocene of South Africa.

78 1.1. Bone functional adaptation

79 Functional interpretations of fossil hominin locomotion largely vary because of a lack of
80 consensus on the functional significance of various external skeletal features. It remains unclear
81 whether ‘primitive’ features represent non-functional evolutionary vestiges, or if they represent

¹ Abbreviations: metatarsophalangeal (MTP); tarsometatarsal (TMT)

82 functional indicators of locomotor behaviour (Stern and Susman, 1983; Clarke and Tobias, 1995;
83 Ward, 2002; Harcourt-Smith and Aiello, 2004; Zipfel et al., 2009). This issue can be partially
84 addressed by studying aspects of bone that are more responsive to external loading. While articular
85 surfaces indicate the joint positions an element is capable of, internal bone is more likely to show the
86 position in which the element was actually loaded (Ruff and Runestad, 1992; Rafferty and Ruff, 1994;
87 Jacobs, 2000; Rubin et al., 2002; Ruff et al., 2006). Diaphyseal cortical bone has been shown to
88 respond to mechanical stress in the shaft and can be indicative of predominant bending forces
89 experienced during loading (Ruff, 1983; Cowin et al., 1985; Doden, 1993; Carlson, 2005; Ruff et al.,
90 2006). However, its function is likely different over joint articular surfaces, where it becomes
91 significantly thinner. It is also covered by cartilage and often contained within a synovial joint.
92 Conversely, the trabecular bone located subchondrally within epiphyses remodels at a faster rate than
93 cortical bone (Eriksen, 2010), and can provide evidence of in vivo loading that may be more useful at
94 reconstructing predominant joint position and associated behaviors (Hodgskinson and Currey, 1990;
95 Rubin et al., 2002; Mittra et al., 2005; Pontzer et al., 2006; Barak et al., 2011; but see Bertram and
96 Swartz, 1991). However, it should be noted that trabecular bone structure does not always correlate
97 with known locomotor patterns in certain mammals, including mice and several primates (Carlson et
98 al., 2008; Ryan and Walker, 2010; Shaw and Ryan, 2012).

99 The current study focuses on two main structural properties of trabecular bone: bone volume
100 fraction (BV/TV), which is a measure of trabecular thickness, number, and spacing, and degree of
101 anisotropy (DA), which reflects the degree to which trabecular struts are oriented in the same
102 direction. These parameters account for 87-89% of the variance in the strength of a bone (Young's
103 modulus) (Maquer et al., 2015), have been shown to change in relation to magnitude, frequency, and
104 direction of load in in vivo studies (Lanyon, 1974; Hodgskinson and Currey, 1990; Biewener et al.,
105 1996; Mittra et al., 2005; Pontzer et al., 2006; Barak et al. 2011), and to differ among taxa that employ
106 different modes of locomotion (MacLatchy and Müller, 2002; Ryan and Ketcham, 2002, 2005; Ryan
107 and Shaw, 2012; Scherf et al., 2013; Tsegai et al., 2013, 2017; but see Fajardo et al., 2007; Ryan and
108 Walker, 2010). BV/TV and DA are informative parameters because both are less likely to scale
109 allometrically and have been found to respond to loading in predictable ways. BV/TV is generally

110 higher in areas that experience greater compressive loading, and trabecular orientation adapts to the
111 main axis of joint movement (Biewener et al., 1996; Guldberg et al., 1997; Ryan and Ketcham, 2002;
112 Mitra et al., 2005; Pontzer et al., 2006; Chang et al., 2008; Polk et al., 2008; Harrison et al., 2011;
113 Saparin et al., 2011). Responses in DA and BV/TV to biomechanical stressors have been
114 demonstrated in several classic studies on the mammalian calcaneus (Lanyon, 1973, 1974; Skerry and
115 Lanyon, 1995; Biewener et al., 1996; Skedros et al., 2004, 2012; Sinclair et al., 2013). In animals in
116 which the calcaneus does not touch the ground during locomotion, trabeculae underlying the Achilles
117 tendon were aligned with the compressive and tensile principal direction of stress (Lanyon, 1974;
118 Biewener et al., 1996). When external loading was removed by detaching the calcaneal tendon,
119 BV/TV reduced as a result of lower trabecular thickness and number (Biewener et al., 1996). Further
120 in vivo studies have supported this. Barak et al. (2011) showed that DA and BV/TV varied
121 predictably in the distal tibiae of sheep that loaded their ankles in different positions. Pontzer et al.
122 (2006) also found strong correlations of DA with changes in external loading at the distal femur of
123 guinea fowl.

124 However, there are several non-mechanical factors that may affect trabecular structure. It is
125 not clear how genetic, hormonal, and environmental factors constrain its structure (Simkin et al.,
126 1987; Judex et al., 2009; Havill et al., 2010; Devlin, 2011; Devlin and Bouxsein, 2012; Devlin et al.,
127 2013), how its response varies based on frequency versus magnitude of mechanical loading (Skerry
128 and Lanyon, 1995; Lambers et al., 2013), as well as anatomical region (Räth et al. 2013; Wallace et
129 al., 2013). Furthermore, by measuring trabecular bone density throughout 9 anatomical regions in
130 humans, Chirchir (2016) found that most sites have homogenous values, suggesting they are
131 influenced by site-specific genetic factors. Nonetheless, computational models (Odgaard et al., 1997;
132 Huiskes et al., 2000; Fox and Keaveny, 2001) and in vivo studies (Lanyon, 1974; Biewener et al.,
133 1996; Pontzer et al., 2006; Barak et al., 2011) have demonstrated strong links between trabecular
134 structure and the frequency, magnitude, and direction in which a joint is loaded.

135 1.2. Biomechanics of the first metatarsal

136 Modern humans are adapted for a bipedal mode of locomotion and possess a forefoot
137 structure in which each metatarsophalangeal (MTP) joint acts as a weight bearing and propulsive
138

139 structure during the push-off part of the stance phase (Stokes et al.,1979; Christensen and Jennings,
140 2009; Griffin et al., 2015). During this phase, the MTP joints dorsiflex, moving the proximal
141 phalanges on to the dorsum of their respective metatarsal heads. This causes tightening of the plantar
142 aponeurosis, stabilizing the foot and elevating the longitudinal arch, which changes its conformation
143 to a stiff lever for propulsion and ultimately toe-off (Hicks, 1954; Bøjsen-Møller, 1979; Susman,
144 1983; Caravaggi et al. 2010; Griffin et al., 2015). As shown by in vivo studies of plantar pressure
145 distribution within the human foot, during dorsiflexion the medial forefoot shows a spike in loading
146 (Hutton and Dhanendran, 1981; Kato et al., 1983; Soames, 1985; Munro, 1987; Lee and Farley,
147 1998; Hunt et al., 2001; Nester et al., 2007; Griffin et al., 2010a). The MT1 bears a large portion of
148 this load and this is reflected by its large head, which experiences high compressive forces during
149 push-off (Rodgers, 1995; Donahue and Sharkey, 1999; Vereecke et al., 2003; D’Août et al., 2004). Its
150 external shape is also designed to stabilize the MTP joint and facilitate dorsiflexion during push-off.
151 The superior aspect of the articular surface of the head expands to the dorsum of the bone, resulting in
152 a raised appearance in relation to its shaft, which is thought to increase the range of dorsiflexion at the
153 MTP joint (Stokes et al., 1979; Susman and Brain, 1988; Susman and de Ruiter, 2004; Griffin and
154 Richmond, 2005; Griffin et al., 2010a). It is also medio-laterally wider on the dorsal aspect of the
155 head than the plantar aspect, which has been argued to enhance joint stability during push-off and
156 facilitate close-packing of the MTP joint (Susman and Brain, 1988; Hetherington et al., 1989; Susman
157 and de Ruiter, 2004; Pontzer et al., 2010, Fernández et al., 2015).

158 Analyzing foot kinematics in extant non-human apes is less straight-forward compared to
159 modern humans because they employ a wider range of locomotion, from terrestrial to arboreal
160 quadrupedalism, vertical climbing, suspension, and occasional terrestrial bipedalism. However, in
161 vivo studies of chimpanzee and bonobo footfall patterns show considerable differences from modern
162 humans (Aerts et al., 2000; Vereecke et al., 2003; D’Août et al., 2004; Griffin et al., 2010a;
163 Wunderlich and Ischinger, 2017). During terrestrial quadrupedal locomotion, bonobos show a higher
164 spike in loading on the lateral aspect of the foot during push-off, with relatively little force inflicted
165 upon the MT1 (Vereecke et al., 2003). Additionally, during vertical climbing, chimpanzees show peak
166 loading under the medial metatarsals, when the MTP joints are plantarflexed (Wunderlich and

167 Ischinger, 2017). If these plantar pressure patterns can be broadly applied to non-human apes, they
168 would suggest that the first MTP joint incurs maximum loading when it is used for grasping.

169 This is reflected within the shape of the MT1 head, which in all non-human apes is
170 mediolaterally expanded on the plantar aspect (Susman, 1983; Latimer and Lovejoy, 1990; Marchi,
171 2005, 2010; Griffin and Richmond, 2010; Fernández et al., 2015). The same mechanism that allows
172 for close-packing of the MTP joint during dorsiflexion in humans allows for close-packing during
173 plantarflexion in non-human apes, increasing stability during pedal grasping (Susman, 1983; Griffin
174 et al., 2010a). It should be noted that within non-human apes, there is variation in how the hallux is
175 used for locomotion. Although comparative plantar pressure distribution data for Gorilla and Pongo
176 do not exist, a substantial amount of information can be obtained through observational studies (Tuttle
177 and Beck, 1972; Cant, 1987; Sarmiento, 1994; Remis, 1995; Gebo, 1996; Doran, 1997; Sarringhaus et
178 al., 2014), skeletal (Susman, 1979; Shea, 1981; Inouye, 1992; Doran, 1993; Marchi, 2005; Richmond,
179 2007; Congdon, 2012; Drapeau and Harmon, 2013; Jashashvili et al. 2015), and soft tissue
180 morphological analyses (Oishi et al., 2012). Such studies show different habitual positioning of the
181 hallux; orangutans generally do not apply significant force on the hallux during suspension, whereas
182 chimpanzees generally do (Oishi et al., 2012). Gorillas do not use their feet for suspension; when they
183 locomote arboreally, their size restricts them to substrates of larger diameters. Their feet are used for
184 vertical climbing or walking, but because the supports they use for climbing are usually large relative
185 to their foot size, there is little flexion of the metatarsophalangeal and interphalangeal joints
186 (Sarmiento, 1994; Remis, 1995).

187 The proximal articular surface of the MT1 is equally reflective of locomotor behavior. Within
188 modern humans, it is relatively broad and flat, corresponding to a stable tarsometatarsal (TMT) joint
189 complex that reduces mediolateral mobility of the hallux, and keeps it in line with the other
190 metatarsals (Morton, 1924; Susman and Brain, 1988; Proctor et al. 2008; Proctor, 2010; Gill et al.
191 2015). Its broad mediolateral width is related to the bending stresses experienced near the base of the
192 MT1, and its increased cross-sectional area is a response to high compressive forces at the joint and
193 high tensile forces inflicted upon the ligaments (Stokes et al., 1979; Griffin and Richmond, 2005). In
194 all other living great apes, the proximal MT1 does not experience such high loading, resulting in a

195 proximal surface that has a smaller overall area. The TMT joint is instead adapted for a wider range of
196 movement associated with grasping and varied locomotion. The proximal articular surface of the MT1
197 is concave, and the distal articular surface of the medial cuneiform is convex, allowing for multiaxial
198 movement of the hallux that is more effective for climbing and grasping (Latimer and Lovejoy, 1990;
199 McHenry and Jones, 2006; Tocheri et al., 2011).

200 1.3. Early hominin locomotion

201
202 Here, we focus specifically on Plio-Pleistocene fossil feet from South Africa, which show a
203 diverse range of morphological features. StW 573, attributed to *Australopithecus prometheus* (but see
204 Berger and Hawks, 2019), shows evidence of a slightly divergent hallux and has been interpreted as
205 adept at tree-climbing (Clarke and Tobias, 1995; Clarke, 2013) but see (Harcourt-Smith et al., 2002).
206 Two isolated MT1s from Sterkfontein (StW 562 and StW 595) suggest there was locomotor diversity
207 in South African hominins. The two metatarsals are of unknown taxonomic status but were both
208 found in Member 4, dated between 2.6 and 2.0 mya (Pickering and Kramers, 2010), and show striking
209 differences in external morphology. StW 562 is described as more human-like based on its distal
210 epiphysis which shows dorsal doming of the head, and because it is relatively robust. StW 595 is
211 relatively gracile and does not show this epiphyseal feature, suggesting this individual had a more
212 ape-like push-off mechanism (Clarke, 2013; DeSilva et al., 2019). Of particular relevance to this
213 study are the postcranial remains of South African robust australopiths attributed to *Paranthropus*
214 *robustus*. *P. robustus* is mainly represented by cranial remains (Grine, 1993; Grine and Daegling,
215 1993; Wood and Constantino, 2007); postcranial remains are relatively abundant, but cannot be
216 attributed with complete confidence to the taxon. Based on pelvic, femoral, and tarsal morphology,
217 the gait of *P. robustus* has been described as bipedal, but with a ‘waddling gait’ and a less efficient
218 body weight transfer mechanism (Napier, 1964; Day and Napier, 1965; Robinson, 1972; Gebo and
219 Schwartz, 2006). However, trabecular properties of the talus (Su and Carlson, 2017) and diaphyseal
220 cortical bone morphology of the fifth metatarsal (Dowdeswell et al., 2017) suggest a medial weight
221 transfer of the foot during push-off and loading of the lateral column in a human-like way.

222 Two complete metatarsals from Swartkrans contribute to our understanding of Early
223 Pleistocene hominin locomotion. SKX 5017 is an isolated left MT1 recovered from the Lower Bank

224 deposit of Swartkrans Member 1, dated to approximately 1.5-1.8 mya (Susman and Brain, 1988;
225 Susman and de Ruiter, 2004). Along with other fossils found within this level, SKX 5017 is attributed
226 to *P. robustus*. The specimen is described as short and similar in length to OH 8 and female bonobos
227 (Susman and Brain, 1988). The base of the metatarsal has a mildly concave and ovoid shape, similar
228 to modern great apes (Susman and Brain, 1988), although the morphology of the base and proximal
229 shaft provide evidence that human-like plantar ligaments (and perhaps an aponeurosis) were present.
230 Based on this basal articular morphology, and on the degree of torsion between the head and the base,
231 there is no indication that the hallux was abducted to an ape-like degree (Susman and Brain, 1988).
232 The head displays a mosaic of primitive and derived features. The superior articular surface of the
233 head extends onto the dorsum of the shaft, which is an indication of increased dorsiflexion at the MTP
234 joint. In contrast, the dorsal medio-lateral breadth of the head is narrower than the plantar breadth,
235 suggesting the joint did not close-pack in dorsiflexion, and thus was less stable during push-off
236 (Susman and Brain 1988).

237 SK 1813 is a nearly complete right MT1 found in a backfill hole of Swartkrans and is thought
238 to have come from Member 1 or 2, but attribution to a specific stratigraphic unit or taxon cannot be
239 made with certainty (Susman and de Ruiter, 2004). Presence of an epiphyseal line near the base
240 signals the subadult status of this individual, with an estimated age of approximately 15 years
241 (Susman and de Ruiter, 2004). It bears strong morphological affinities to SKX 5017, albeit the former
242 is smaller. It has the same dorsal mediolateral narrowing on the head, and expansion of the dorsal
243 articular surface onto the dorsum of the shaft. The base is also dorsoplantarly expanded, which is
244 reflective of increased tensile forces from well-developed plantar ligaments in response to a bipedal
245 gait (Susman and de Ruiter, 2004; Proctor et al. 2008; Proctor, 2010). The shape of the proximal
246 articular surface is difficult to discern due to post-mortem damage, but is nonetheless described as
247 concave and ovoid, typical of non-human apes (Susman and de Ruiter, 2004). In this study, we
248 examine trabecular structure within the epiphyses of these two specimens to reconstruct aspects of
249 their biomechanical loading regime and in doing so make inferences about the locomotor behaviours
250 of the individuals they represent.

251 1.4. Previous trabecular analysis of the MT1

252 Predictions about how mechanical loading affects the trabecular bone within the MT1 can be
253 made a priori based on currently-known patterns within the MT1 head of *Homo sapiens*, *Pan*
254 *troglodytes*, *Pan paniscus*, and *Gorilla gorilla* (Griffin et al., 2010b). Volume of interest (VOI)-based
255 analysis has shown that modern humans exhibit significantly higher DA values than non-human apes,
256 consistent with a tightly constrained joint with a relatively uniaxial range of movement. The same
257 study has shown BV/TV to be less effective at differentiating locomotor behavior between species,
258 but this may be caused by the methodological limitations of using VOIs in analyzing trabecular
259 structure. Overall, these results suggest that among trabecular bone properties, a high degree of
260 anisotropy is the most indicative factor of a forefoot habitually used for propulsion during bipedal gait
261 (Griffin et al. 2010b).

262 1.5. Aims and predictions

263
264 Based on known loading patterns within the forefoot of modern humans and great apes, and the
265 mechanical adaptations of trabecular bone, we test the following hypotheses:

- 266 1. Modern humans will have a higher BV/TV within the dorsal aspect of the MT1 head and
267 base, and non-human apes will display the opposite pattern. This corresponds to the position
268 in which the joints close-pack and incur the highest compressive load.
- 269 2. Modern humans will show higher overall DA and non-human apes will show lower overall
270 DA within the entire element, corresponding to the range of motion at the TMT joint and the
271 MTP joint. We also predict that modern humans will show relatively higher DA in the dorsal
272 regions of the epiphyses compared to the non-human apes.
- 273 3. Based on their external morphology, we hypothesize that SKX 5017 and SK 1813 will show
274 similar trabecular distribution to modern humans. However, because of a more concave and
275 rounded proximal articular facet in SKX 5017 indicative of a relatively mobile joint, its base
276 will have a lower DA than modern humans.

277 To ensure no confounding factors relating to body size, we also test for interspecific allometry in
278 trabecular bone variables. Following the results of previous studies on the talus and tibia of modern
279 humans and chimpanzees (Tsegai et al., 2017), and on the lower limbs of modern humans (Saers et al.

280 2016), we predict that there will be no significant allometric scaling between any trabecular parameter
281 and bone size. Furthermore, because Tsegai et al. (2017) found that the tibia and talus do not show the
282 same patterns of scaling in regards to Tb.Th., BV/TV, or DA, we expect that the MT1 will also
283 display allometric patterns not displayed in either element.

284 **2. Methods**

285 2.1. Sample

286 The comparative sample consists of thirty-nine MT1s from modern non-human apes and
287 modern humans: six Pongo sp., ten Gorilla gorilla, ten Pan troglodytes, and eleven Homo sapiens.
288 Details of the study sample are shown in **Table 1**. Orangutans were wild-shot, but their provenance is
289 unknown, with the exception of one captive male from the Munich Zoo. Gorillas were all wild-shot in
290 Cameroon and the French Congo. Some chimpanzee specimens were collected from the Taï National
291 Park, Republic of Côte d'Ivoire; others were wild-shot in Cameroon. The modern human sample was
292 composed of likely sedentary and shod individuals from two 19th-20th century cemeteries in
293 Göttingen, Germany (for more information on the comparative sample, see SI, Table S1). Specimens
294 were chosen if the individuals were adult, free from signs of pathology, and if their trabecular bone
295 was well-preserved. Adult status was determined based on external morphology of the associated
296 postcrania and dental eruption. Additional information on individual specimens is provided within the
297 supplemental online information. Two fossil hominin MT1s were obtained from the Ditsong National
298 Museum of Natural History and derive from the site of Swartkrans, South Africa. One is attributed to
299 Paranthropus robustus (SKX 5017), and the other being of unassigned taxonomic status (SK 1813).
300 SKX 5017 is complete and well-preserved, but because of extensive cortical and trabecular damage to
301 the base of SK 1813, only the head was analyzed.

302 2.2. Image Acquisition

303 Specimens were scanned at the Max Planck Institute for Evolutionary Anthropology in
304 Leipzig and at Cambridge University. The modern Homo and Pongo specimens were scanned using a
305 Diondo d3 high-resolution micro-CT system in Leipzig with an acceleration voltage of 140 kV, and
306 120 μ A and 140 μ A respectively, using a 0.5 mm brass filter. The images were reconstructed as 3000
307 x 3000 16 bit tiff image stacks from 3240 projections with two frame averaging. The Taï Forest Pan

308 troglodytes sample was scanned using a Skyscan 1173 with an acceleration voltage of 100 kV and 62
309 μA using a 1.0 mm aluminium filter. The images were reconstructed from 2240 x 2240 16 bit tiff
310 image stacks from 2400 projections with two frame averaging. Gorilla gorilla and Pan troglodytes
311 specimens from the Powell-Cotton Museum were scanned using a Nikon Metrology XT H 225 ST
312 High resolution CT scanner in Cambridge University. They were scanned at an acceleration voltage of
313 135 kV and 135 μA with no filter. The images were reconstructed as 2000 x 2000 16 bit tiff image
314 stacks from 1080 projections with one frame averaging. All specimens were scanned with an
315 isometric voxel resolution between 27 and 42 μm .

316 2.3. Specimen segmentation

317 Scans were segmented into binary format using the Ray Casting Algorithm (RCA) (Scherf
318 and Tilgner, 2009). This method is most effective where there is clear separation between bone and
319 air, and where there is little matrix within the epiphysis. All extant taxa, along with SKX 5017 were
320 segmented using this method. Due to a large amount of matrix within the epiphysis of SK 1813, it was
321 segmented using a machine learning clustering algorithm that is most effective where there is matrix
322 that falls within the greyscale range of trabecular bone (Dunmore et al., 2018). This algorithm assigns
323 voxels in an image to one of three predefined classes, based on the probability that its greyscale value
324 would be in each class. Therefore, it allows for segmentation of problematic areas that the RCA does
325 not handle effectively.

326 2.4. Medtool

327 The segmented images were processed through a customized script within medtool v4.2
328 (www.dr-pahr.at), a python-based script manager. Each step of this method has been described by
329 Pahr and Zysset (2009) and tested by Gross et al. (2014). Using the segmented image (**Fig. 1a**), the
330 outer surface (**Fig. 1b**), and inner surface (**Fig. 1c**) were defined and subtracted from one another to
331 create an image of the cortex only (**Fig. 1d**). An image of the trabecular bone (**Fig. 1e**) only was
332 obtained by subtracting the cortex image from the original segmented image. A series of mask
333 overlays were created to separate the cortical and trabecular bone, and 'inside air' from 'outside air'
334 by assigning them to different grey values (**Figs. 1f, g, h**). A 3D mesh of the mask images was

335 obtained using the computational geometry algorithms library (CGAL version 4.10, Computational
336 Geometry, <http://www.cgal.org>), a mesher that creates a 3D finite element model using 3D Delauney
337 triangulation (Delaunay, 1934). Trabecular bone was analyzed through the placement of multiple
338 spherical VOIs onto a rectangular background grid of 2.5 mm grid spacing over the MaskSegIn image
339 (**Fig. 1f**). VOIs were placed at each node with a set diameter of 5 mm to ensure overlap. Trabecular
340 parameters were measured within each VOI, and values were assigned to each grid node. These
341 values were then interpolated to the tetrahedral elements, resulting in BV/TV and DA color maps that
342 were visualized using Paraview 3.14.1 (Sandia Corporation, Kitware. Inc).

343 Within each VOI, bone volume fraction (BV/TV) was calculated as the ratio of bone voxels
344 to bone and air voxels. The trabecular orientation (second rank fabric tensor) was calculated using the
345 Mean Intercept Length (MIL) method (Whitehouse, 1974; Odgaard, 1997). This gave results for first,
346 second, and third eigenvectors and eigenvalues. Fabric degree of anisotropy (DA) was calculated as (1
347 – [eigenvalue 3/eigenvalue 1]), resulting in numbers from 0 to 1 (representing complete isotropy and
348 anisotropy, respectively). The values within each VOI were averaged to obtain results for the entire
349 section. In addition to BV/TV and DA, trabecular thickness (Tb.th., mm), trabecular number (Tb.N,
350 mm⁻¹), and trabecular spacing (Tb.S, mm) were calculated within each VOI.

351 2.5. Statistical analysis

352 Because the focus of this research is on trabecular bone structure, statistical analysis was
353 confined to the epiphyses; the shaft, which contains little to no trabeculae was separated from the head
354 and base. In each scan, the head was separated where the articular surface on the plantar aspect
355 terminated, as it is clearly delineated from the shaft. When viewing the element in plantar view, each
356 metatarsal displays a pronounced curvature on the proximal and medial aspect of the shaft. The cut for
357 the base was made where this curvature was most pronounced (**Fig. 2a**). The base and the head were
358 further separated into dorsal and plantar regions by taking their maximum dorso-plantar length and
359 dividing it by half (**Fig. 2b**).

360 Statistical analysis was performed using RStudio v1.0.153 (RStudio Inc. 2015), and plots
361 were generated using ggplot2 (Wickham, 2009). All trabecular variables were tested for allometry

362 using reduced major axis regression, through the R package lmodel2 (Legendre, 2018). Because data
363 for body size was unavailable for the study sample, the geometric mean for each specimen was used
364 as a proxy for body size. This was calculated using five linear measurements of the metatarsal as
365 proposed by De Groote and Humphrey (2011), which included maximum MT1 length, as well as
366 dorsoplantar and mediolateral length of the proximal and distal articular surfaces.

367 Standard non-parametric tests were used because of small sample sizes, and because not all
368 regions in all taxa showed a normal distribution. Pair-wise comparisons using Mann-Whitney U tests
369 were conducted to investigate intraspecies differences in BV/TV and DA between the dorsal and
370 plantar sections in the head and base. The raw dorsal and plantar BV/TV and DA values were also
371 compared between species using Kruskal-Wallis tests to test whether the samples originate from the
372 same distribution. Additionally, BV/TV values in both epiphyses were used to calculate the ratio of
373 trabecular bone in the plantar versus dorsal regions. Ratios were compared between taxa using a
374 pairwise Wilcoxon rank sum test with a Bonferroni correction. In addition to traditional non-
375 parametric tests, differences between the BV/TV ratios of each taxon were evaluated for statistical
376 significance using a standard resampling method (i.e., bootstrapping), which is well-suited to examine
377 differences between means of groups with varying and small sample sizes (Efron and Tibshirani,
378 1993). Values from each taxon were resampled with replacement 10,000 times, from which 10,000
379 BV/TV ratio means were generated. Using pairwise comparison, the bootstrapped means from all taxa
380 were randomly aligned and subtracted from means from another taxon, resulting in 10,000 differences
381 between the means. Pairwise comparison was also used to calculate the difference between the means
382 of the original, non-bootstrapped samples. The bootstrapped differences were then compared to the
383 original differences. The number of times the difference between the bootstrapped means exceeded
384 the difference between the original sample means represents a proportion that is analogous to a p-
385 value of a one-tailed test.

386 Bootstrap analysis was also applied to the fossil sample to determine the likelihood that their
387 BV/TV ratios fell within those of the extant taxa. In this case, the BV/TV ratio from the fossil was
388 included within each extant taxon's sample, which was then resampled and replaced. The number of

389 times the fossil's BV/TV ratio fell within the range of the bootstrapped mean BV/TV ratios represents
390 the likelihood that this value would be expected within a sample from the study taxa.

391 **3. Results**

392 3.1. Allometry

393 Most trabecular parameters showed no significant allometric scaling within taxa (**Table 2**).
394 Gorilla showed positive scaling of trabecular thickness and a negative scaling of trabecular number.
395 However, while this correlation was significant for trabecular thickness ($p < 0.05$), the confidence
396 intervals of the slope contained the isometric scaling value, meaning isometry cannot be rejected. The
397 same pattern is seen in modern humans, though none of the scaling is significant. Pan shows
398 significant positive and negative allometric scaling of trabecular spacing and number, respectively.
399 Pongo shows positive scaling for trabecular thickness and negative scaling for trabecular spacing.
400 However, it shows no significant allometric scaling. In all taxa, BV/TV and DA both show a positive
401 relationship with increased MT1 size, but without any significant positive allometric scaling. Pan
402 presents a single exception, wherein BV/TV has a negative relationship with MT1 size, though it is
403 not statistically significant. This allows for the conclusion that BV/TV and DA are not strongly linked
404 to MT1 size (and by proxy, body size). Given the fact that BV/TV does not scale allometrically in any
405 taxon, it can be concluded that body size, and by extension sex do not affect patterns of trabecular
406 distribution to a significant degree.

407 3.2. MT1 BV/TV distribution

408 **Figure 3** shows BV/TV distribution maps of a representative specimen from each taxon
409 within the sample (images of the full sample are shown within the supplementary information, Figs. 1
410 – 4). Modern humans consistently show a greater distribution of trabecular bone within the dorsal
411 aspect of the head. However, some individuals have higher BV/TV values closer to the centre of the
412 epiphysis or near the cortical/trabecular boundary. BV/TV tends to be higher on the lateral side of the
413 dorsal aspect, corresponding with the slightly valgus orientation of the phalanges in relation to the
414 metatarsal shaft. Additionally, specimens show a consistent pattern on the plantar surface of the head
415 wherein the trabecular bone directly below the articular surface for the sesamoid bones displays lower

416 BV/TV (see SI, Fig. S4). The ventral keel between the articular surfaces has generally higher BV/TV.
417 All modern humans have higher BV/TV on the dorsal half of the MT1 base; the plantar aspect has
418 relatively little trabecular bone, with the exception of a small area near the insertion site of the
419 fibularis longus tendon, which is more pronounced in modern humans than in non-human apes.

420 All non-human apes within the sample tend to exhibit a higher concentration of trabecular
421 bone within the plantar region of the head, with Pongo showing the most plantar concentration. Pan
422 and Gorilla show relatively similar distributions to each other; trabecular bone has a higher
423 concentration on the plantar aspect of the head, but it is further from the subchondral boundary than in
424 Pongo. However, in all taxa, there is variability in the extent to which the trabecular bone extends into
425 the centre of the distal epiphysis: some individuals have a fairly localized concentration near the
426 subchondral bone, but others show a much deeper distribution within the entire epiphysis (e.g., see SI
427 Figs 1-3). The pattern of trabecular bone distribution within the base is variable, but overall it is
428 evenly distributed across the dorsal and plantar regions. Pongo shows a pattern in which the edges of
429 the articular surface show higher BV/TV (see Fig. 2), with relatively less trabecular bone in the center
430 of the epiphysis. In all non-human apes, the trabecular bone is distributed along an oblique plane in
431 relation to the shaft, corresponding to the plane in which the metatarsal flexes and extends.

432 **Figures 4 and 5** illustrate the external morphology and trabecular distribution of SKX 5017
433 and SK 1813, respectively. Similar to modern humans, the dorsal region of the metatarsal head of
434 SKX 5017 exhibits a higher distribution of trabecular bone than the plantar region; although it is
435 located more dorsally than is generally found within modern humans. This region of high BV/TV is
436 positioned laterally and corresponds to a slightly valgus orientation of the phalanges in relation to the
437 shaft. The remainder of the head shows an even distribution of trabecular bone, with an area of
438 slightly higher BV/TV on the plantar aspect on the ventral keel between the articular surfaces for the
439 sesamoid bones (this is also seen in some modern humans). The base of SKX 5017 shows high
440 BV/TV near the dorso-medial border of the articular surface, similar to where it is seen in several
441 non-human apes, and a slight area of high BV/TV on the plantar-lateral aspect. Both plantar and
442 dorsal regions display high BV/TV, in contrast to modern humans which have a markedly higher and
443 more localized trabecular bone distribution within the dorsal region.

444 SK 1813 (**Fig. 5**) also displays higher trabecular bone distribution within the dorsal aspect of
445 the head, though it is more centralized within the epiphysis than in SKX 5017 or the modern human
446 sample. Additionally, the area immediately below the cortical/trabecular boundary shows a sharp
447 decrease in BV/TV. On the plantar aspect, where the shaft meets the head, there is another area of
448 high BV/TV. When comparing the color map to the original CT scan, it becomes apparent that this
449 area of high BV/TV is the result of cortical bone from the shaft extending into thick trabecular struts
450 within the head, similar to Pan and Gorilla. However, SK 1813 shows relatively less trabecular bone
451 within the rest of the plantar surface, resulting in a different overall distribution to all other taxa.

452 3.3. Regional trabecular distribution

453 Mean values for all trabecular parameters are shown in **Table 3**, and **Figure 6** presents box-
454 and-whisker plots of BV/TV values among the study taxa. Within extant taxa, BV/TV tends to be
455 highest in Pan and lowest in modern humans. Furthermore, modern humans show the highest overall
456 DA values, and Pongo displays the lowest. It should be noted that coefficients of variation (CV)
457 indicate that Pongo has the most variable BV/TV and DA values (with the exception of BV/TV in the
458 modern human base). When considering overall patterns across both epiphyses, trabecular thickness is
459 highest in Gorilla and lowest in modern humans. Trabecular number shows the opposite pattern: it is
460 highest in modern humans and lowest in Gorilla. Trabecular spacing is highest in Gorilla; of the
461 extant sample, it is lowest in modern humans. When considering the base and head separately,
462 different patterns emerge between taxa. Although BV/TV is similar between the head and base, all
463 extant non-human apes show a relatively higher number, and more tightly spaced trabeculae in the
464 base than in the head. In all cases, BV/TV remains similar in both epiphyses as a result of thinner
465 trabecular bone in the base. We also see a difference in DA between the head and base: despite some
466 overlap in values, mean DA is higher in the base than in the head. In contrast, modern humans show a
467 similar trabecular architecture in the head and in the base. Trabecular number is slightly higher in the
468 head, resulting in higher BV/TV, but to a lesser extent than the non-human apes.

469 The two fossils show a different trabecular bone structure from each other, as well as to the
470 comparative sample. SKX 5017 exhibits the highest overall BV/TV of all taxa as a result of a

471 relatively higher number of thicker and closely spaced trabeculae. Similar to the non-human apes, it
472 has a relatively higher number, and more closely spaced trabeculae in the base than in the head. SK
473 1813 shows a BV/TV value that falls well within the range of the African great apes. Its trabecular
474 number is higher, and its trabecular spacing is lower than all other taxa. Its trabecular thickness falls
475 within the range of all taxa. Both fossils have closely spaced trabeculae, but compared to SKX 5017,
476 SK 1813 has a higher number of thinner trabeculae. Disregarding their absolutely thicker trabeculae
477 than modern humans, the MT1 heads of the fossil specimens have an overall higher number of closely
478 spaced trabeculae, a pattern seen in the head of modern humans; SKX 5017 shows values in the base
479 within the range of non-human apes.

480 Regional summary statistics for all analyzed trabecular parameters can be seen in the SOM
481 (SOM Table S1). Mann-Whitney U tests reveal significant differences in mean BV/TV values
482 between the dorsal and plantar regions of the MT1 heads of all studied taxa (Fig. 6). Non-human apes
483 show a higher BV/TV within the plantar region, whereas modern humans have higher BV/TV in the
484 dorsal region. Within the base of the MT1, only modern humans show significant differences in
485 BV/TV between the dorsal and plantar regions, with relatively higher values in the dorsal region.
486 SKX 5017 shows higher BV/TV in the dorsal regions of the head and base, similar to modern
487 humans, but with overall higher BV/TV. The SK 1813 head displays overall higher BV/TV in the
488 dorsal region as well, though it has absolutely lower BV/TV than SKX 5017.

489 **Figure 7** presents ratios of dorsal-to-plantar BV/TV within the heads and bases of all taxa.
490 Within all non-human apes, the base of the metatarsal shows a BV/TV ratio approximating a value of
491 one, indicating relatively equal BV/TV between the dorsal and plantar regions. In contrast, modern
492 humans display a much higher ratio, indicating relatively higher BV/TV within the dorsal section of
493 the base. Within the head, all extant non-human apes show a ratio below one, indicating relatively
494 higher BV/TV within the plantar region, whereas modern humans retain a higher proportion of
495 trabecular bone within the dorsal region. Results from post-hoc pairwise Wilcoxon rank sum tests
496 from the head reveal significant differences between the BV/TV ratio of modern humans and all
497 extant non-human apes ($p < 0.0005$), and between Gorilla and Pongo ($p < 0.01$) (**Table 4**). No
498 statistically significant differences were found between Pongo and Pan, or between Gorilla and Pan.

499 Within the base, no statistically significant differences were found in BV/TV ratio between the non-
500 human apes, but all showed significant differences from modern humans ($p < 0.0005$). Bootstrap
501 analyses support these results, showing a similar distribution of trabecular bone within the base of all
502 non-human apes (see SI Fig. S6).

503 Results from bootstrap analyses of BV/TV ratio means in the base reveal significant
504 differences between the BV/TV ratio of SKX 5017 and all extant taxa, with a value lower than
505 modern humans ($p < 0.01$), and higher than Pongo ($p < 0.01$), Gorilla ($p < 0.01$), and Pan ($p < 0.01$) (**Fig.**
506 **8**). Bootstrap analyses from the head show that the BV/TV ratio of SKX 5017 falls within the range of
507 modern humans ($p > 0.05$), and that the BV/TV ratio of SK 1813 falls outside the range of all extant
508 taxa ($p < 0.01$). The distribution, though more dorsal than plantar, falls below the range seen in modern
509 humans, and above the range seen Pongo, Gorilla, and Pan (**Fig. 9**).

510 Differences in DA values between taxa are illustrated in **Figure 10**. All taxa show significant
511 differences between DA in the plantar and dorsal regions, with modern humans showing the absolute
512 highest values, and Pongo the lowest. Results from the Kruskal-Wallis post hoc test for differences in
513 DA show that modern humans have significantly higher DA in the head than all taxa, and
514 significantly higher DA in the base than Pongo and Gorilla. Among the non-human apes, only Pan
515 and Pongo differ significantly in the head. In the base, Pan is the only significantly different taxon,
516 with the highest mean DA value (**Table 5**). There is no statistically significant interspecies difference
517 in the ratio of DA between the dorsal and plantar regions. All modern taxa display a pattern where the
518 dorsal sections of both epiphyses possess similar DA values that are significantly higher than the
519 values seen in the plantar sections. Like the modern taxa, SKX 5017 displays higher DA in the dorsal
520 regions, however, DA in the dorsal region of the base is absolutely higher than DA in the dorsal
521 region of the head, and DA in the plantar region of the base is absolutely higher than the plantar
522 region of the head. The plantar region of the base and the dorsal region of the head share close values,
523 a pattern not seen in the entire extant sample. SK 1813 displays a similar DA pattern to the extant
524 taxa, with higher values in the dorsal region than in the plantar region, although it has the absolute
525 lowest values.

526 **Figures 11 and 12** display bivariate plots of BV/TV and DA values from the head and base,
527 respectively. Modern humans possess lower BV/TV and higher DA, distinguishing them from other
528 taxa. Within the non-human apes, Pan shows overall higher DA, followed by Gorilla and Pongo,
529 respectively, but their BV/TV values overlap. As mentioned earlier, Pongo shows the widest range of
530 BV/TV values. BV/TV values in both SKX 5017 and SK1813 are well above those in modern
531 humans, and within the range of the non-human apes. DA values are lower in SK 1813 and SKX 5017
532 than in modern humans, though they are absolutely lowest in the former, within the range of Pongo.

533 **4. Discussion**

534 4.1. Effect of body size on trabecular bone structure

535
536 Most trabecular parameters do not to scale allometrically within species. Like other studies
537 (Doubé et al., 2011; Ryan and Shaw, 2013), results from this analysis show a positive, but isometric
538 relationship between BV/TV and body size. The only taxon to show positive scaling of trabecular
539 thickness is Gorilla, supporting previous findings (Doubé et al., 2011). However, because the
540 confidence intervals of the slope contain the isometric scaling value, an isometric relationship cannot
541 be rejected. All other taxa show no allometric scaling of trabecular thickness (see also Mullender et
542 al., 1996; Swartz et al., 1998). In Pan, trabecular spacing shows positive allometric scaling and
543 trabecular number shows negative allometric scaling. These results contradict previous studies of
544 trabecular allometry in primates (mainly in the femur and humerus), which emphasize negative
545 allometric scaling of trabecular spacing and thickness (Ryan and Ketcham, 2002, 2005; Fajardo et al.,
546 2007; Ryan and Walker, 2010; Ryan and Shaw, 2012). This could be the result of smaller sample
547 sizes used in this study, or because this study observes interspecies allometry. Our results are partially
548 consistent with a previous study on allometry between Pan and Homo (Tsegai et al., 2017). Certain
549 trabecular variables of the MT1 show similar scaling patterns as the talus, but others are more
550 consistent with the distal tibia. Overall, these results suggest that scaling within species as a result of
551 individual size variation and sexual dimorphism do not play an important role in trabecular structure,
552 and that different elements throughout the skeleton may show variable allometric scaling patterns.

553 4.2. Trabecular distribution in extant taxa

554 Within the extant sample, the trabecular parameters that most effectively separate each
555 locomotor mode are relative BV/TV and absolute DA. Trabecular bone acts as structural support
556 during joint loading, meaning higher BV/TV should be located in the area of the epiphysis where the
557 joint incurs high compressive loading (Rubin et al., 2002; Barak et al., 2011). A higher distribution of
558 trabecular bone in the plantar region offers support for loading during plantarflexion, and a higher
559 distribution in the dorsal region offers support for loading during dorsiflexion. The first hypothesis is
560 that modern humans show higher BV/TV within the dorsal aspect of the epiphyses. This is supported
561 here based on significantly higher BV/TV ratio in the MT1 of modern humans than all other extant
562 taxa, which corresponds to its higher range of dorsal excursion, and to the position in which the MTP
563 joint incurs maximum loading (Rodgers, 1995; Donahue and Sharkey, 1999; Vereecke et al., 2003;
564 D’Août et al., 2004). Furthermore, the tarsometatarsal joint, which is more limited in mobility than
565 the MTP joint, is stable and experiences movement along a single plane (Morton, 1924; Susman and
566 Brain, 1988; Proctor et al. 2008; Gill et al. 2015). Therefore, it exhibits a tightly constrained pattern
567 within the base of the MT1.

568 Within the head, non-human apes show a plantar distribution of trabecular bone associated
569 with high compressive loading during plantarflexion. This corresponds to studies of plantar pressure
570 distribution in *Pan troglodytes* (Wunderlich and Ischinger, 2017), which show that the MTP joint
571 incurs peak plantar pressure during vertical climbing, when it is plantarflexed. Plantar pressure data
572 on *Pongo* during suspensory locomotion is entirely absent, making inferences about loading at its
573 MTP joint speculative. However, results from this study suggest that it was nonetheless loaded higher
574 in plantarflexion than dorsiflexion. Although the *Pongo* hallux is less capable of force gripping
575 compared to *Gorilla* and *Pan*, its actual use during suspensory locomotion may not be as limited as
576 previously thought. Commonly held ideas emphasize that *Pongo* show reduced hallucal recruitment
577 during suspensory locomotion (Morton, 1924; Midlo, 1934; Tuttle and Rogers, 1966; Tuttle, 1969;
578 Marchi, 2010), however, there is evidence that its true use is somewhat underreported (McClure et al.,
579 2012).

580 The great apes, which have a more mobile tarsometatarsal joint, show evenly distributed
581 BV/TV within the entire base. This could be reflective of the variable ways in which these taxa load

582 the forefoot, resulting in a generalized trabecular structure adapted for a wide range of motion and
583 loading. Despite similar BV/TV ratios, color maps show differences in the distribution of trabecular
584 bone within the base of Pongo, Gorilla, and Pan. As mentioned earlier, trabecular bone within the
585 Pongo base shows a higher distribution near the edges of the articular surface, whereas Gorilla and
586 Pan show a relatively higher distribution throughout the entire epiphysis. This could be related to
587 locomotor differences between the taxa. Pongo employs a hook-like grip during suspension without
588 applying significant force on its hallux, contrary to Pan and Gorilla, which both use the hallux more
589 forcefully (Sarmiento, 1994; Remis, 1995; Oishi et al., 2012). The low compressive and tensile forces
590 experienced by the Pongo MT1 base might explain why the trabecular bone does not extend as far
591 into the centre of the epiphysis. This could mean that BV/TV ratio is better at differentiating broad
592 locomotor patterns (i.e., between bipedalism and vertical climbing), whereas BV/TV color maps may
593 better capture subtle differences in joint positioning and loading between types of terrestrial
594 quadrupedalism or arboreal locomotion.

595 Griffin et al. (2010b) analyzed the trabecular structure within the MT1 head of Pongo,
596 Gorilla, Pan, and Homo. By placing three VOIs in the epiphyses, they found that all taxa showed
597 higher BV/TV in the dorsal region of the head. Based on these results, they concluded that BV/TV
598 was not useful in differentiating habitual joint positioning. Results from this study contradict these
599 results. Though BV/TV ratio is not useful in differentiating locomotion between non-human apes, it
600 separates bipedalism from all other forms of locomotion. The reason for these conflicting results
601 could be methodological. Although overall, non-human apes show higher BV/TV in the plantar region
602 of the head, there is variation in where within the epiphysis BV/TV is highest. Some specimens show
603 higher trabecular distribution near the subchondral bone, and others show higher distribution deeper
604 within the epiphysis (and our results indicate that concentrations are not always in the midline of the
605 joint). Thus, VOIs restricted to only a portion of the epiphysis capture only a subset of the variation
606 compared to a whole-epiphysis approach.

607 It is also worth noting that BV/TV ratio is likely better at differentiating between broad
608 locomotor modes because absolute BV/TV does not necessarily reflect the magnitude of load applied
609 to an element. Modern humans show systematically lower BV/TV than all other taxa, despite their

610 medial forefoot experiencing higher loading during push-off than non-human apes (Vereecke et al.,
611 2003). Lower overall BV/TV has been previously observed in other studies of cortical and trabecular
612 bone in modern humans (Lieberman, 1996; Chirchir et al., 2015; Saers et al., 2016; Tsegai et al.,
613 2017) and has been suggested to be linked to higher sedentism in relation to early hominins and recent
614 hunter-gatherers. Because the sample represented in this study is of likely shod and sedentary modern
615 humans, it is also worth noting that the low overall BV/TV values seen here may not reflect the entire
616 range of human variation (Shaw and Stock, 2009a, b; 2013; Ryan and Shaw, 2015; Saers et al., 2016).
617 For this reason, in this study, BV/TV is mainly relevant when its relative distribution is analyzed.
618 Further studies including shod and unshod populations, as well as hunter-gatherers may contribute to
619 our understanding of overall BV/TV within modern humans.

620 The second hypothesis is that modern humans show higher DA within the MT1 than all non-
621 human apes, and that this is most apparent in the dorsal regions. This is partially supported; modern
622 humans show overall higher DA than Gorilla and Pongo throughout both epiphyses, but they do not
623 differ significantly from Pan in the base. Nevertheless, higher overall DA within modern humans
624 corresponds with the hypothesis that a more uniaxial range of movement will result in stereotypically
625 oriented trabeculae. Similar to Griffin et al. (2010b), we found that all taxa show higher DA dorsally,
626 suggesting that non-biomechanic factors may influence this trabecular variable. As such, caution
627 should be applied when inferring locomotor behavior based on DA alone. Within non-human apes,
628 DA values overlap, meaning the modes of locomotion employed by these taxa cannot be as clearly
629 differentiated using DA. For example, given the fact that Gorilla is considered the most terrestrial
630 taxon, it is noteworthy that it is most similar in DA to Pongo, the most arboreal taxon. This may also
631 be explained by different factors; Gorilla may simply load its hallux in variable positions, or the
632 individuals in this sample may have been relatively arboreal. There is evidence that western lowland
633 gorillas display considerable arboreal behavior, with females spending more time on terminal
634 branches at frequencies similar to Pan (Remis, 1995, 1999). Because the gorillas in this study are all
635 western lowland, there is the possibility that they were also relatively arboreal. Ultimately, there may
636 be substantial overlap in degree of arboreality between non-human apes, making DA fairly weak in
637 differentiating their locomotor modes. These results simply demonstrate that modern humans have the

638 least variable MT1 positioning. In order to associate DA with a specific mode of locomotion, it may
639 be more informative to look at directionality of trabeculae as opposed to overall DA or DA ratio. DA
640 is a measure of how similarly aligned trabeculae are in relation to each other, but does not provide
641 information on which axis the trabeculae are aligned in. Because trabeculae orient themselves along
642 the principal axis of movement, the actual direction in which they are aligned might be more
643 informative in reconstructing movement in a joint (Biewener et al., 1996; Ryan and Ketcham, 2002;
644 Pontzer et al., 2006; Saporin et al., 2011). Future analyses could map, in the same manner as absolute
645 values of trabecular variables, regional differences in primary trabecular orientation throughout the
646 epiphysis.

647 Similarities in trabecular patterning between non-human apes are emphasized when plotting
648 DA against BV/TV. The head shows considerable overlap in values; Gorilla overlaps with Pongo and
649 Pan in both variables. Combined, modern humans do not show overlap in DA and BV/TV with the
650 other taxa, but their values are close. This could be due to the fact that the range of motion at the MT1
651 head is limited to flexion and extension, meaning all taxa show a similar range of movement here. DA
652 in the base distinguishes taxa better; this could be because the TMT joint may better reflect
653 differences in hallucal positioning. The problem with this explanation is that modern humans and Pan
654 show similar DA in base, despite known differences in joint loading and positioning at the TMT joint.
655 Perhaps Pan loads this joint along a relatively constrained axis, although further observational and
656 biomechanical analyses would have to be performed to test this. It is also worth noting that non-
657 human apes show overall higher DA in the base than the head, whereas modern humans show similar
658 values in both epiphyses. This could be reflective of the fact that the former load their proximal and
659 distal MT1 joints in variable positions, contrary to relatively constrained modern human MT1.

660 Despite broad similarities in BV/TV and DA between non-human apes, differences can be
661 observed between them when comparing other trabecular parameters (Tb.Th., Tb.Sp., Tb.N.). Gorilla
662 displays relatively few, thick, and widely spaced trabeculae, whereas Pongo is characterized by
663 relatively more, thinner, and closely spaced trabeculae. Pan shows values intermediate between
664 Pongo and Gorilla. Of the non-human apes, the overall pattern in Pongo is most similar to modern
665 humans, which have the thinnest trabeculae, but are similar in number and spacing. However, these

666 differences in trabecular properties among species may not be significantly different and small sample
667 sizes may not reflect overall patterns within species; furthermore, the functional implication of these
668 differences, if any, is unknown.

669 4.3. SKX 5017 and SK 1813

670 The original descriptions of SKX 5017 and SK 1813 (Susman and Brain, 1988; Susman and
671 de Ruiter, 2004) suggest that both have a combination of primitive and derived features, and that
672 based on multivariate analyses of various linear measurements, both were most similar to modern
673 humans. Additional multivariate analysis has suggested a unique mode of locomotion in both
674 specimens characterized by relatively facultative bipedalism (Zipfel and Kidd, 2006). Research on the
675 proximal articular surface of both specimens has differentiated them from modern humans (Proctor et
676 al., 2010) and from one another (Vernon, 2013). Proctor et al. (2010) measured the curvature of the
677 surface using 3D geometric morphometric analysis, and found that SK 1813 did not group with
678 modern humans but showed affinities to SKX 5017. Based on an ‘ape-like’ curvature, both were
679 interpreted as belonging to *Paranthropus*. Another analysis groups SKX 5017 with Pan and western
680 gorillas in terms of mediolateral articular surface curvature, and SK 1813 with modern humans and
681 *Papio* (Vernon, 2013). Based on these conflicting results, it is difficult to determine how ‘human-like’
682 or ‘ape-like’ the proximal articular surface is, and even less so the locomotor behavior associated with
683 this shape.

684 The third hypothesis is that the two fossils will show similar trabecular distribution to modern
685 humans, but that the base of SKX 5017 will show lower DA than in modern humans due to its
686 relatively concave proximal articular facet. This is partially supported: based on its BV/TV ratio, SKX
687 5017 shows a similar trabecular distribution to modern humans in the head, but its base displays a
688 more even dorso-plantar trabecular distribution. As predicted, DA within the base of SKX 5017 is
689 lower than in modern humans. Similar to modern humans and SKX 5017, the SK 1813 head shows a
690 BV/TV ratio over one, indicating a dorsal distribution of trabecular bone. However, the ratio is
691 significantly lower than in modern humans; in fact, it falls outside the range of all taxa within the
692 comparative sample. Based on the color maps, SKX 5017 shows evidence of an MTP joint that was
693 loaded in hyper-dorsiflexion. The external morphology of the head, specifically its raised superior

694 aspect in relation to the dorsum of the shaft, indicates it was capable of a wide range of dorsiflexion at
695 the MTP joint (Susman and Brain, 1988). However, because of its dorsal mediolaterally narrow
696 width, previous analyses have not reached a consensus on how the joint was loaded. It has been
697 suggested that this combination of features prevented close-packing in dorsiflexion at the MTP joint,
698 and resulted in instability during bipedal locomotion (Susman and Brain, 1988; Susman and de Ruiter,
699 2004). Though bootstrap analysis places SKX 5017 BV/TV ratio well within the range of modern
700 humans, the color maps suggest the element was not loaded in the same way. SKX 5017 shows a
701 hyper-dorsal distribution of bone not seen in modern humans. Because this is not seen in any of the
702 comparative taxa, it cannot be linked with confidence to a specific type of locomotion. This may fit in
703 with previous suggestions that the joint was less stable during dorsiflexion: because the joint did not
704 close-pack in dorsiflexion it hyper-extended, resulting in a more dorsal trabecular distribution. When
705 taking into account other trabecular parameters (i.e., DA), it could imply a form of locomotion not
706 seen in modern taxa. For example, this concentration of trabecular bone could be caused by habitual
707 hyper-dorsiflexion at the MTP joint from foot placement that is directly against a vertical substrate.
708 This has been noted to occur in arboreal contexts in modern human populations that collect resources
709 from trees and is directly associated with extreme dorsiflexion of the ankle and forefoot (Kraft et al.,
710 2014). Research on midfoot flexibility in modern humans has also shown that lateral midfoot plantar
711 pressure is strongly correlated to the magnitude of midfoot flexion, and that individuals with higher
712 lateral midfoot plantar pressure tend to have increased dorsiflexion at the hallucal MTP joint (Bates et
713 al., 2013; DeSilva and Gill, 2013; DeSilva et al., 2015). How the trabecular bone in the MT1 of such
714 individuals is structured is not known. However, this suggests that hyper-dorsiflexion at the MTP
715 joint of SKX 5017 could be the result of a fairly mobile midfoot lacking a human-like arch.

716 The trabecular structure of the base of the SKX 5017 MT1 combined with its external
717 morphology emphasize a different loading pattern from modern humans. Susman and Brain (1988)
718 described the hallux as adducted based on their description of the base as relatively flat and
719 superoinferiorly orientated. However, geometric morphometric analyses have shown that it shares
720 morphological affinities to Gorilla, including a relatively oblique curvature and a concave surface,
721 albeit to a lesser extent (Proctor et al., 2008). Ultimately, because we don't have a complete P.

722 robustus foot, it is difficult to tell with certainty whether it was abducent or adducted. However,
723 results here show that the base does not adhere to a completely modern human-like trabecular
724 structure. Though SKX 5017 has a higher ratio of trabecular bone within the dorsal aspect, there is
725 relatively more trabecular bone within the plantar region than is observed in modern humans. As a
726 result, the BV/TV ratio within the base of SKX 5017 is lower than in modern humans, but higher than
727 is observed in all other non-human apes. The higher BV/TV ratio in the head suggests the element
728 was loaded in dorsiflexion. However, the relatively lower ratio in the base suggests it could have still
729 been loaded in plantarflexion. Combined with the fact that the proximal articular surface is concave
730 compared to modern humans, this could be reflective of a TMT joint that has retained adaptations for
731 grasping. DA within the base also suggests the TMT joint was more mobile than in modern humans: it
732 is within the range of Gorilla, Pan, and Pongo, and like these taxa, is higher within the base than the
733 head. This implies that the two epiphyses were capable of differential movement, and that unlike in
734 modern humans, the element was not tightly constrained at both joints.

735 Additional trabecular parameters emphasize the unique nature of its trabecular structure.
736 Though its trabecular thickness is within the range of modern great apes, SKX 5017 shows a structure
737 in the head characterized by a high number of closely spaced trabeculae, which is seen in the head of
738 modern human MT1s. Trabecular parameters within the base fall within the range of modern non-
739 human apes. The functional implication of this is not certain, but it emphasizes the unique trabecular
740 structure of SKX 5017: it is more ‘human-like’ in the head, and more ‘ape-like’ in the base.

741 It is worth noting that there is a prominent osteophyte on the dorsal aspect of the shaft,
742 proximal to the articular surface of the head. This could be the result of a traumatic injury sustained in
743 life, or a condition called hallux rigidus, which produces exostoses on the head of the first metatarsal
744 (Susman and Brain, 1988). However, this condition is accompanied with flexed interphalangeal joints,
745 which conflicts with the distribution of trabecular bone in the metatarsal head that indicates a
746 dorsiflexed rather than plantarflexed MTP joint.

747 Similar to modern humans and SKX 5017, SK 1813 shows a more dorsal trabecular
748 distribution in the head, which is reflective of a joint that was habitually loaded in dorsiflexion. It has
749 been described by Susman and de Ruiter (2004) as similar in morphology and function to SKX 5017;

750 both metatarsals have a short, strait shaft, and medio-laterally narrow dorsal aspect of the head.
751 However, the trabecular structure reveals considerable differences between the two specimens. SK
752 1813 displays BV/TV that is absolutely lower than SKX 5017, within the range of Pongo, Gorilla,
753 and Pan, and a lower DA, closer to the range of Pongo. The distribution of trabecular bone, though
754 more dorsal than plantar, falls equally between the ranges of non-human apes and modern humans,
755 meaning it does not conform to any modern pattern. It is difficult to interpret joint positioning of SK
756 1813 accurately because only the head was analyzed, and because it is a subadult. Though modern
757 humans retain a relatively consistent locomotor mode throughout ontogeny (Sutherland et al., 1980;
758 Beck et al., 1981; Raichlen et al., 2015: but see Zeininger et al., 2018), juvenile and subadult gorillas,
759 chimpanzees, and bonobos display much more arboreal behavior than adults (Doran, 1997;
760 Sarringhaus et al., 2014). Trabecular structure is known to change throughout ontogeny (Ryan and
761 Krovitz, 2006; Gosman and Ketcham, 2009; Raichlen et al., 2015; Saers, 2017) especially in regards
762 to DA (Gosman and Ketcham, 2009; Abel and Macho, 2011). Because its taxonomic affiliation and
763 life history are uncertain, it is not known whether its locomotor repertoire was as variable throughout
764 ontogeny as modern apes, or as constrained as modern humans. It is possible that this hominin would
765 have loaded its hallux in variable positions based on its lower BV/TV ratio than modern humans, and
766 that it experienced multiaxial loading based on its low DA.

767 Additionally, SK 1813 displays the absolute highest trabecular number and the lowest
768 trabecular spacing, which is a pattern seen in modern humans and SKX 5017. The taxonomic
769 affiliations of both specimens are currently uncertain; analyses of the external morphology have
770 provided contradictory opinions (Susman and Brain, 1988; Susman and de Ruiter, 2004; Proctor et al.,
771 2010; Vernon, 2013). Here, we have shown that the BV/TV ratios between the two fossils are
772 considerably different, implying different types of MTP joint loading. However, all other trabecular
773 parameters represent a normal range of variation when compared to the intraspecies variation in other
774 living taxa. Based on these results, we can only suggest that these hominins incurred different joint
775 loading during locomotion.

776 4.4. Interpretation of Paranthropus locomotion

777 Debates about australopith and Paranthropus locomotion have emphasized different types of
778 locomotion based on conflicting morphological evidence that shows derived features adapted for
779 bipedalism, and primitive features indicative of climbing and pedal grasping (Stern and Susman,
780 1983; Susman et al., 1984; Susman and Brain, 1988; Grine and Susman, 1991; Susman and de Ruiter,
781 2004). Research on *P. robustus* locomotion is fairly limited because postcranial fossils are scarce and
782 often not securely attributed to the taxon. Its postcranial morphology is described as gracile and of
783 small stature (McHenry, 1991), and its locomotion has been described as bipedal with a ‘less
784 efficient’ gait compared to modern humans (Napier, 1964; Robinson, 1972). Additionally, its radial
785 morphology has been suggested to indicate retained arboreal abilities (Grine and Susman, 1991).
786 Recently, the locomotor behavior of *P. boisei* has been characterized by combined terrestrial
787 bipedalism and occasional arboreality based on scapular, radial, humeral, femoral, and tibial
788 morphology (Dominguez-Rodrigo et al., 2013; Green et al., 2018). If Paranthropus represents a
789 monophyletic group, it is possible that *P. robustus* would have had similar postcranial morphology to
790 *P. boisei*. However, the efficacy of using postcranial elements in determining phylogenetic association
791 is uncertain; additionally, despite potentially monophyletic status, postcranial morphology between
792 the two species could vary based on differing ecological niches.

793 Recently, research on *P. robustus* pedal elements (TM 1517) has supported the idea of an
794 overall bipedally adapted foot. Trabecular structure in the talus has been shown to display increased
795 DA in parts of the element associated with a medial weight shift during the stance phase, and by
796 extension a human-like bipedal gait (Su and Carlson, 2017). Nonetheless, interpretations are still
797 uncertain: higher BV/TV in the lateral region was suggested to indicate a degree of lateral loading
798 intermediate in magnitude between modern human and anthropoid tali. However, diaphyseal cross-
799 sectional properties of an MT5 from Swartkrans (SKX 33380) suggest human-like loading in the
800 lateral column of the foot (Dowdeswell et al., 2017). Although, as with other Swartkrans postcranial
801 elements, it should be noted that this MT5 is not linked to *P. robustus* with absolute certainty.
802 Cumulatively, analyses of Paranthropus locomotion based on trabecular structure and external
803 morphology show features that suggest habitual bipedalism, with an indication that the overall
804 structure of the foot was more mobile, allowing for multiaxial movement at the MTP and TMT joints

805 (Napier, 1964; Robinson, 1972; Susman and Brain, 1988; Susman and de Ruiter, 2004; Dominguez-
806 Rodrigo et al., 2013; Dowdeswell et al., 2017; Su and Carlson, 2017).

807 Based on patterns of BV/TV and DA within the metatarsal, there is evidence that the
808 Paranthropus foot (associated with SKX 5017) possessed a habitually dorsiflexing MTP joint that
809 was capable of a relatively multiaxial range of movement. The taxonomic status of SKX 5017 is
810 reasonably-well established, as the layer in which it was found (Member 1) is represented by more
811 than 95% Paranthropus remains (Susman and Brain, 1988). We do not know exactly how its external
812 morphology compares to early Homo MT1s, meaning we cannot rule out the possibility that this
813 element belongs to early Homo. Susman and Brain (1988) have emphasized its morphological
814 similarities with OH 8, and others have noted that the SKX 5017 base is more similar to *A. afarensis*
815 (A.L. 333-54), suggesting it belongs to a different taxon than early Homo (Proctor, 2008; Vernon,
816 2013). However, either possibility is uncertain since we do not know the definite taxonomic status of
817 OH 8 (DeSilva et al., 2010). Therefore, these interpretations can only be applied to *P. robustus* with
818 reasonable certainty. It is not certain whether SK 1813 represents *P. robustus* as well, but the
819 trabecular structure of the two fossil specimens is different in BV/TV ratio and DA, indicating
820 different habitual joint loading. However, we refrain from making taxonomic attributions to SK 1813
821 based on trabecular structure alone. If the trabecular pattern preserved here represents its adult
822 structure, it could indicate two different species (*P. robustus* and *Homo* sp.), but enough is not known
823 about Paranthropus and early Homo postcranial variability to make that claim. Furthermore, if the
824 trabecular structure seen in SK 1813 reflects a subadult mode of locomotion that differs from adult
825 locomotion, it may very well represent the same species as SKX 5017 at an earlier ontogenetic stage.

826 **5. Conclusions**

827 Studies of trabecular bone structure have provided mixed results in its utility in inferring habitual
828 joint positioning (Ryan and Ketcham, 2002; Fajardo et al., 2007; DeSilva and Devlin, 2012).
829 However, it is possible that elements in closer contact to the substrate may be more reflective of
830 locomotor behavior because they directly absorb compressive loads associated with ground reaction
831 forces (Maga et al., 2006; Kivell, 2016). The MT1 shows particular promise because it is a relatively
832 simple element with adjacent joints that show a consistent range of motion. Results from this study

833 strengthen its application in inferring fossil hominin locomotion by providing evidence that its
834 trabecular structure can be linked to habitual joint positioning and loading of the forefoot within an
835 extant ape sample. The most apparent differences are seen between modern humans and all other non-
836 human apes, indicating that the relatively constrained and stable structure of the human foot results in
837 specific trabecular patterning. BV/TV reflects the position in which the joint experiences the highest
838 load, and DA reflects its range of motion. Though these parameters do not statistically differentiate
839 variation in non-human ape locomotion, obligate bipedalism presents clear signals. Human bipedal
840 locomotion is reflected in the dorsally distributed and anisotropic trabecular bone structure in the
841 MT1, while the more arboreally adapted non-human MT1 exhibits more plantarly distributed, and
842 relatively less anisotropic trabecular bone. This study also highlights the importance of trabecular
843 bone analysis in the context of paleoanthropology. The two fossil specimens, which have been
844 described as highly similar in external morphology, present different trabecular bone structures that
845 would imply variable modes of locomotion. We find that the MTP joint was loaded differently in the
846 two specimens: one in hyper-dorsiflexion, and the other in a manner intermediate between modern
847 humans and non-human apes. Whether this is due to ontogenetic or phylogenetic factors is unknown.
848 Ultimately, we show that trabecular bone structure can be associated with known modes of
849 locomotion in modern taxa, and that it can be informative in in reconstructions of fossil hominin
850 behavior.

1409

1410

1411

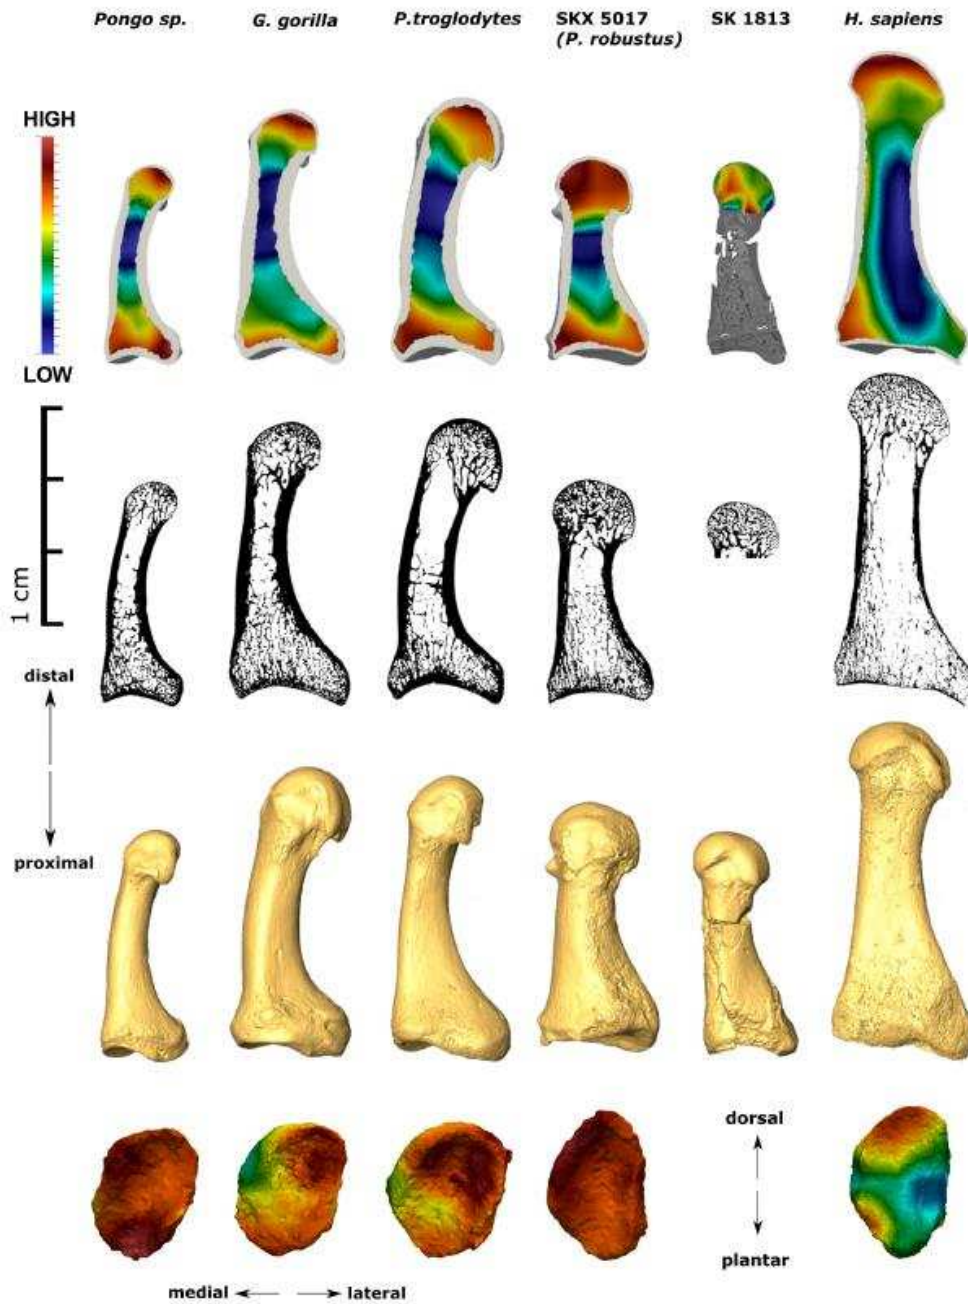

1412

1413 Figure 1. Masking procedure used to segment different components of bone. Illustrated here is a
 1414 Gorilla first metatarsal that has undergone complete segmentation. From left to right: (a) segmented
 1415 image; (b) outer mask; (c) inner mask; (d) cortical mask; (e) trabeculae only image; (f) MaskSeg In;
 1416 (g) MaskSeg Out; (h) MaskSeg (this is the mask which is used for trabecular quantification by
 1417 medtool).

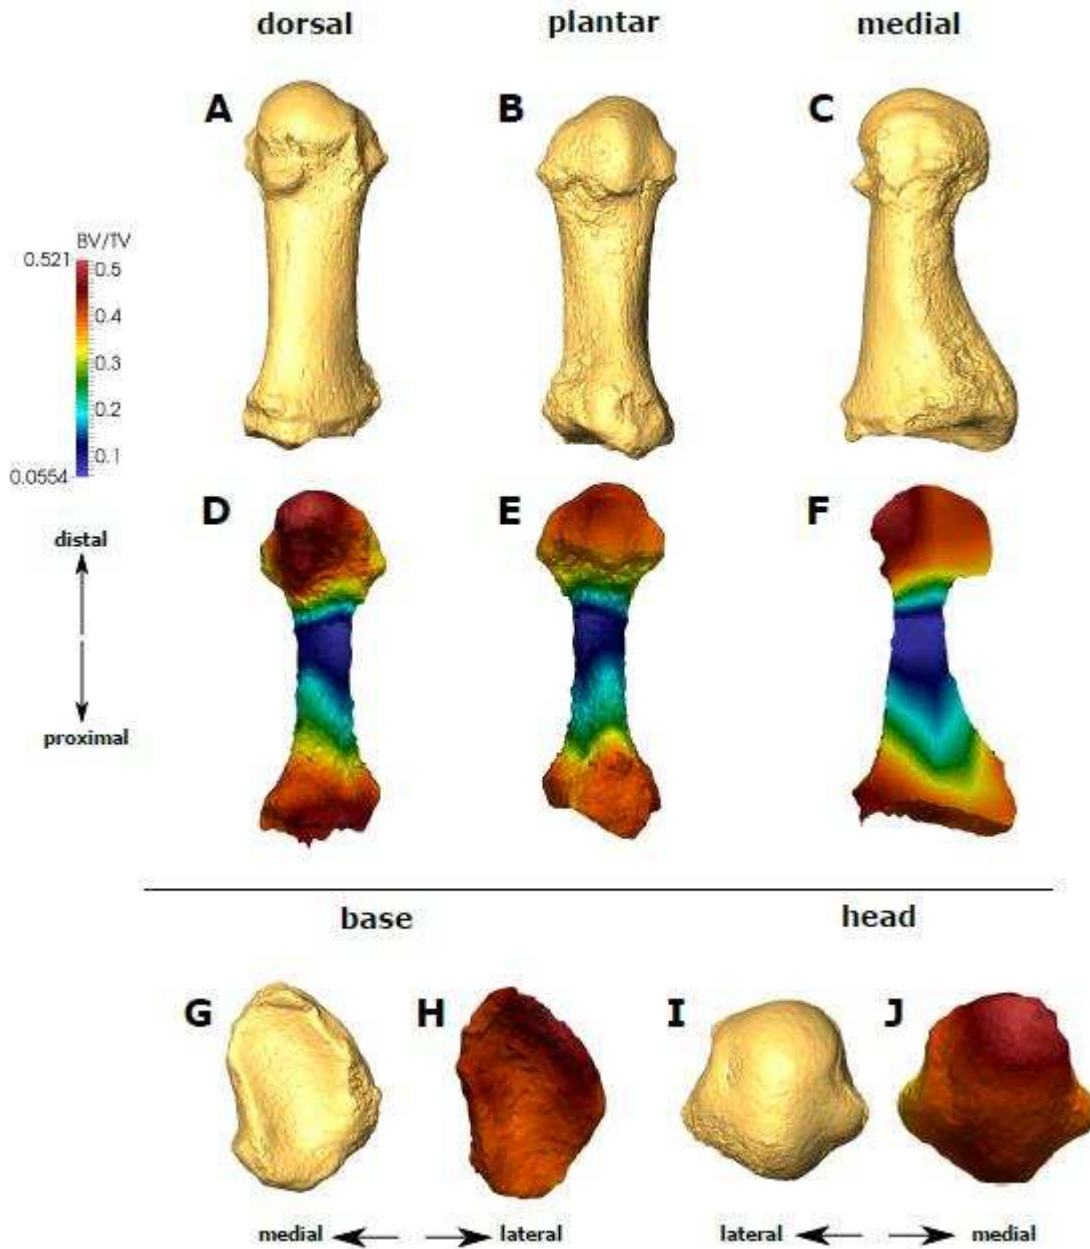

1418

1419 Figure 2. Delineation of the epiphyses and the dorsal and plantar sections. (a) The head was
1420 delineated where the articular surface terminates on the plantar aspect of the bone. Proximally, the
1421 base was delineated based on a homologous curvature on the medial aspect of the shaft (indicated by
1422 the arrow). (b) Both the base and the head were separated into dorsal and plantar sections by dividing
1423 in half the maximum dorso-plantar width.

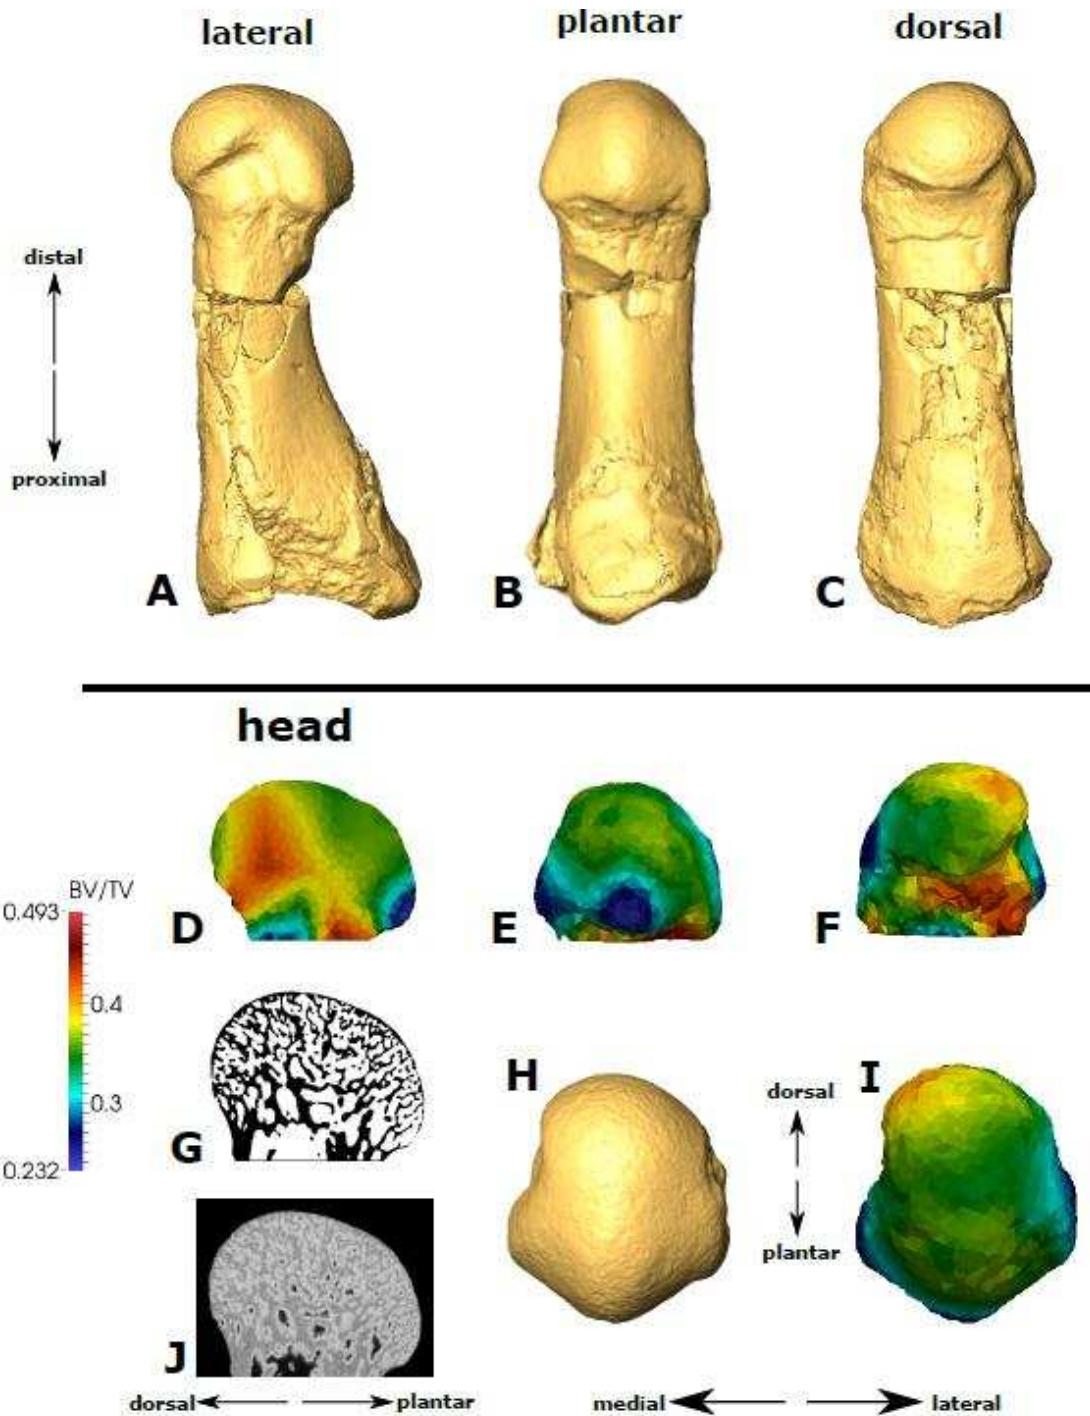

1424

1425 Figure 3. Representative specimens from each taxon. From top to bottom: BV/TV color maps of MT1
 1426 sagittal cross-section, segmented images, isosurfaces of external bone, and BV/TV color maps of
 1427 proximal articular surfaces. BV/TV color maps are scaled to individual specimen ranges to visualize
 1428 patterns of trabecular distribution as opposed to overall differences in BV/TV values. The first three
 1429 rows are scaled to represent actual size differences between taxa. The color maps on the fourth row
 1430 are all scaled to the same size, and do not represent natural size. SKX 5017 base on bottom row is
 1431 mirrored to match the side of all other specimens.

1432

1433 Figure 4. SKX 5017. Isosurfaces showing the external morphology of the element (a, b, c, g, i), and
 1434 color maps of trabecular bone BV/TV (d, e, f, h, j). Images over the line show overall trabecular
 1435 distribution throughout the whole bone in different positions, and images below the line display the
 1436 dorso-plantar trabecular distribution in the epiphyses.

1437

1438 Figure 5. SK 1813. Isosurfaces showing the external morphology of the element (a, b, c, h). Images a,
 1439 b, and c display the damage to the shaft and proximal aspect of the bone. Below the line are various
 1440 visualizations of the metatarsal head. Illustrated are color maps of trabecular bone BV/TV (d, e, f, i).
 1441 Notice the relatively dorsal position of high BV/TV, which is most clearly seen in the sagittal cross-
 1442 section (d). This is also noticeable when viewing the element on its plantar (e), dorsal (f), and distal
 1443 aspects (i). Also shown is the segmentation (g), and the original CT scan (j) of the head.

1444

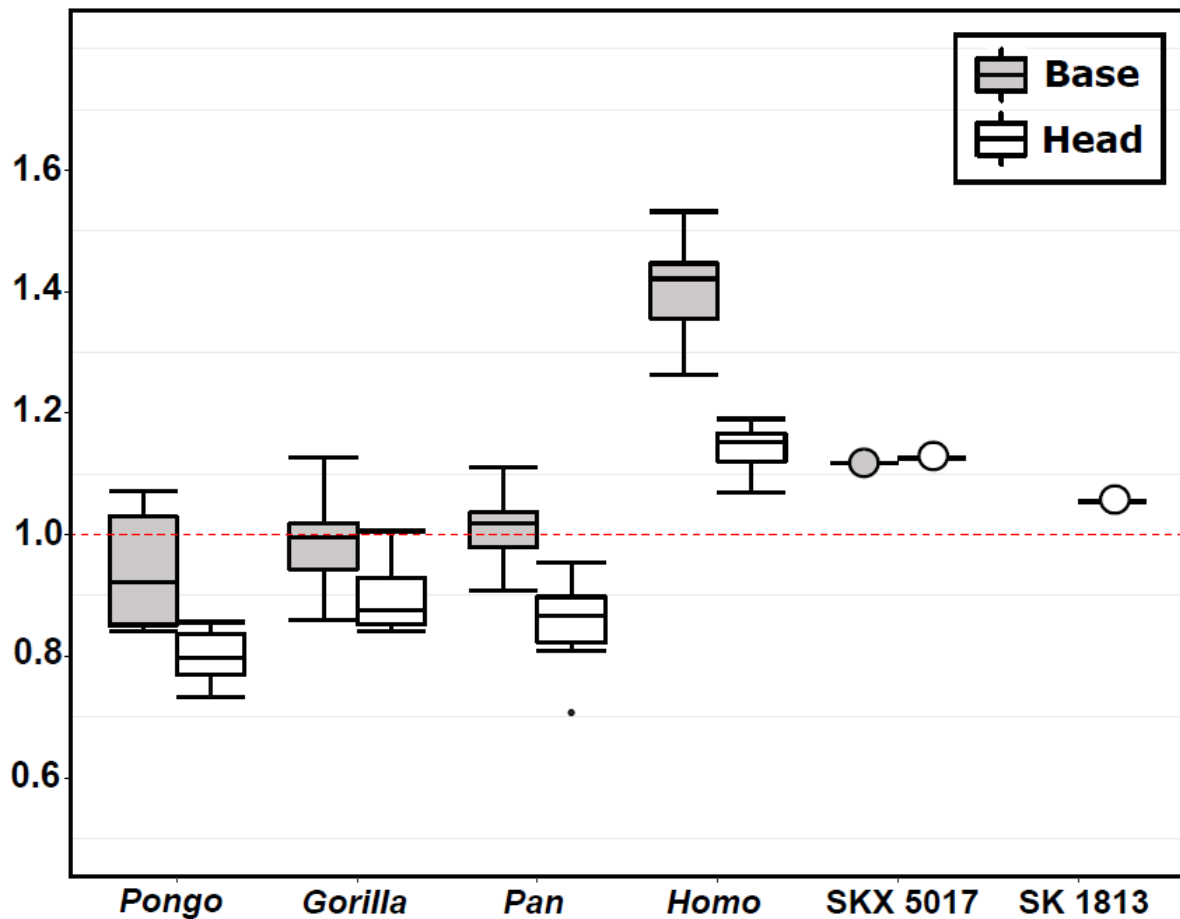

1445 Figure 6. Boxplot showing raw BV/TV values within each analyzed region and each taxon.

1446 Significant differences in pairwise comparisons are denoted using asterisks [(*) = $p < 0.05$; (**) =

1447 $p < 0.005$; (***) = $p < 0.001$]. Within the base none of the non-human apes show significant differences

1448 between dorsal and plantar regions, whereas modern humans do. All taxa show significant differences

1449 between the dorsal and plantar regions of the head.

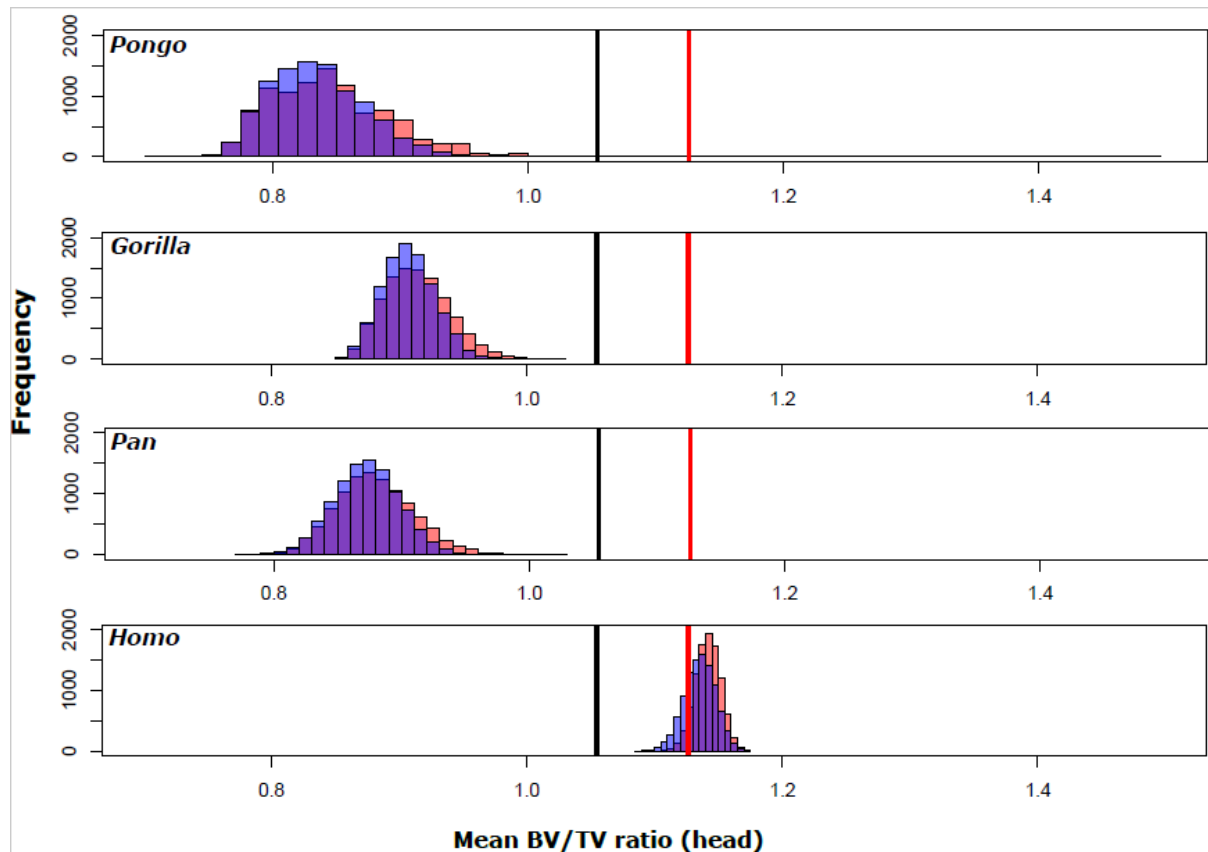

1450

1451 Figure 7. Boxplot of BV/TV ratio within the base and head of each taxon. Ratio represents the relative
 1452 trabecular distribution; this is obtained by dividing dorsal values by plantar values and multiplying by
 1453 100. A ratio over one represents a more dorsal distribution and a ratio under one represents a more
 1454 plantar distribution. Red dotted line represents an equal dorso-plantar distribution of trabecular bone.

1455

1456 Figure 8. Bootstrap plots showing the resampled and redistributed sample means of BV/TV ratio
 1457 within the base of each taxon. The red line represents the original BV/TV ratio of SKX 5017. Its
 1458 position in the histograms represents the likelihood that the mean BV/TV ratio of the fossil hominins
 1459 will fall within the range seen in modern taxa. In all cases, the red line falls outside the range of
 1460 modern taxa.

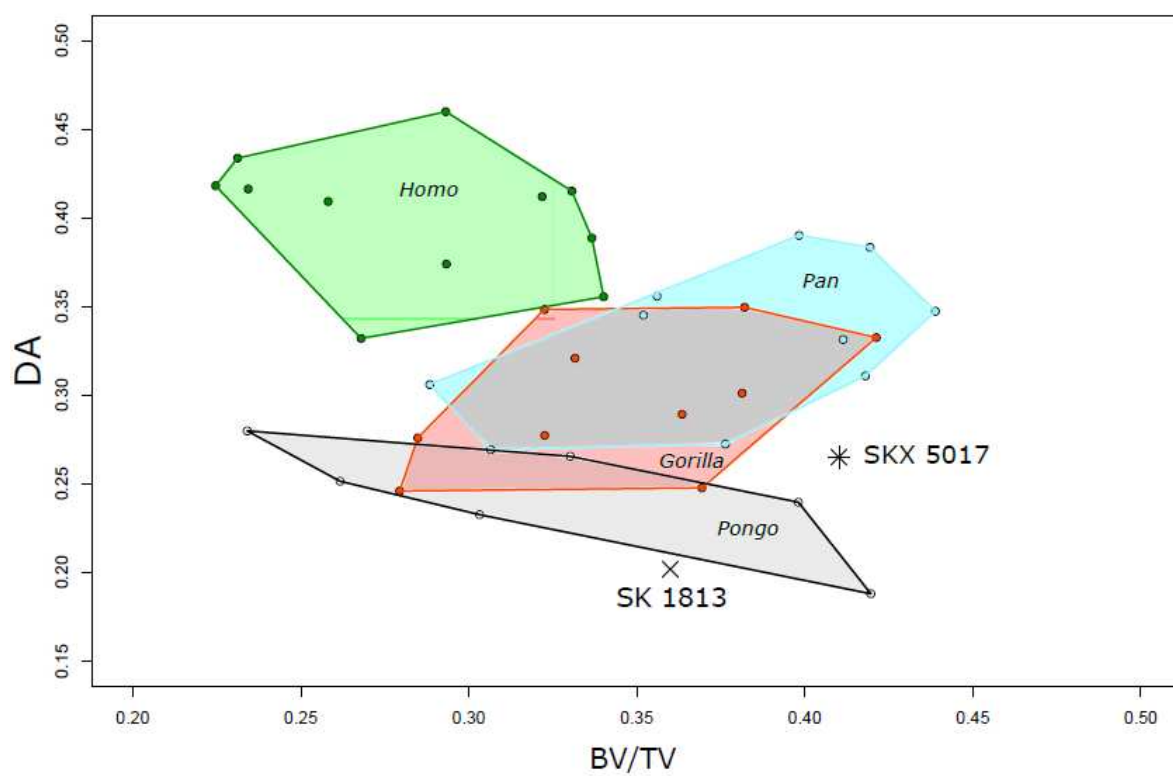

1461

1462 Figure 9. Bootstrap plots showing the sample means of BV/TV ratio within the head of each taxon.
 1463 Pink bars represent the modern samples resampled and redistributed with SKX 5017; blue bars
 1464 represent modern samples resampled and redistributed with SK 1813; purple bars represent overlap
 1465 between the two samples. The red line represents the original BV/TV ratio of SKX 5017 and the black
 1466 line represents the original BV/TV ratio of SK1813. The BV/TV ratio of SK 1813 falls outside the
 1467 range of all taxa, with the exception of Pongo. The BV/TV ratio of SKX 5017 falls within the range
 1468 of modern humans.

1469

1470 Figure 10. Boxplot showing raw DA values within each analysed region and each taxon. Significant
 1471 differences in pairwise comparisons are denoted using asterisks (*) = $p < 0.05$; (**) = $p < 0.005$; (***) =
 1472 $p < 0.001$). All taxa display significantly higher DA in the dorsal regions of the element. Overall,
 1473 modern humans show the absolute highest DA, and SK 1813 shows the lowest.

1474

1475 Figure 11. Scatterplot showing DA and absolute BV/TV values for the heads of all taxa. Dorsal and
 1476 plantar regions have been combined to illustrate patterns in the entire epiphysis.

1477

1478 Figure 12. Scatterplot showing DA and absolute BV/TV values for the bases of all taxa. Dorsal and
 1479 plantar regions have been combined to illustrate patterns in the entire epiphysis.
