ABSTRACT

Class II methanol (CH₃OH) masers are amongst the clearest signposts of recent high-mass star formation (HMSF). A complete catalogue outlines the distribution of star formation in the Galaxy, the number of young star-forming cores, and the physical conditions of their environment, made possible by the Global View on Star Formation (GLOSTAR) survey. This blind survey of the radio regime of 4–8 GHz maps the Galactic mid-plane in the radio continuum, 6.7 GHz methanol line, the 4.8 GHz formaldehyde line, and several radio recombination lines. We present an analysis of the observations of the 6.7 GHz CH₃OH maser transition using data from the D-configuration of the Very Large Array (VLA). We analysed data covering Galactic longitudes from $-2^\circ < l < 60^\circ$ and Galactic latitudes of $|b| < 1^\circ$. We detected a total of 554 methanol masers, out of which 84 are new, and we catalogued their positions, velocity components, and integrated fluxes. With a typical noise level of ~ 18 mJy beam⁻¹, this is the most sensitive unbiased methanol survey for methanol masers to date. We also searched for dust continuum and radio continuum associations, finding that 97% of the sources are associated with dust and 12% are associated with radio continuum emission.

Key words. masers – surveys – ISM: molecules – radio continuum: ISM – radio lines: ISM – stars: formation

1. Introduction

The Global View on Star Formation (GLOSTAR) survey (Brunthaler et al. 2021) is an unbiased survey observing the Galactic plane with the *Karl G. Jansky* Very Large Array (VLA) in D- and B-configurations and the Effelsberg 100 m radio telescope in order to find and characterise star-forming regions in the Milky Way. Thanks to its sensitivity and high angular resolution, the data contain a wealth of information that has already been used to catalogue new radio sources (Medina et al. 2019), identify supernova remnants (SNR; Dokara et al. 2021), and find new methanol (CH₃OH) masers in the Cygnus X region (Ortiz-León et al. 2021).

In studying high-mass star formation (HMSF), methanol masers have proven to be indispensable. Interstellar methanol

maser emission was first discovered by Barrett et al. (1971) at 25 GHz towards Orion-KL. Since then, many other methanol maser lines have since been discovered, such as those at 6.7 and 12.2 GHz (Batra et al. 1987; Menten 1991b). These are divided into two types based on their pumping mechanism: collisional (Class I: Batrla et al. 1987; Cragg et al. 1992; Voronkov et al. 2010, 2014; Leurini et al. 2016) or radiative (Class II: Menten 1991a,b; Caswell et al. 2010). In particular, Class II CH₃OH masers have already proven to be one of the clearest signposts of HMSF, with the 6.7 GHz transition being the brightest and most widespread in the Galaxy (Menten 1991b, 1993; Walsh et al. 1997, 1998). Second only to the 22.2 GHz H₂O maser in its intensity and abundance, methanol maser emission at 6.7 GHz is unique in that it exclusively traces high-mass star forming regions (Minier et al. 2003; Ellingsen 2006; Xu et al. 2008). The 6.7 GHz line from the $5_1-6_0A^+$ transition of the methanol molecule requires specific conditions in order to begin masing. These are met in the surrounding dust and gas of massive young stellar objects (MYSOs) with densities greater than 10^6 cm⁻³ and temperatures > 150 K (e.g. Sobolev & Deguchi 1994; Cragg et al. 2005) due to the intense

^{★★} Member of the International Max Planck Research School (IMPRS) for Astronomy and Astrophysics at the Universities of Bonn and Cologne.

radiation of the MYSOs. While some of the earliest detections of Class II methanol masers were made toward ultra-compact HII regions, namely, the archetypical W3(OH) (Batra et al. 1987; Menten et al. 1992), it was found that in fact very few of these methanol masers have radio continuum counterparts (Walsh et al. 1998; Beuther et al. 2002; Urquhart et al. 2013, 2015; Hu et al. 2016; Billington et al. 2019). It is thus clear that most 6.7 GHz methanol masers probe MYSOs located in regions of recent high-mass star formation. Locating and studying them can provide further insights into the distribution of these regions in the Galaxy and characterise their properties.

Given their usefulness in the study of high-mass star formation, many targeted surveys (e.g. Menten 1991b; MacLeod et al. 1992; Caswell et al. 1995; Caswell 1996; Ellingsen et al. 1996; van der Walt et al. 1996; Walsh et al. 1997; Ellingsen 2007; Yang et al. 2019b) and unbiased surveys (Rickert et al. 2019; Pestalozzi et al. 2005; Pandian et al. 2007; Caswell et al. 2010, 2011; Green et al. 2010, 2012; Breen et al. 2015; Ortiz-León et al. 2021) have been performed, culminating in over 1000 Class II 6.7 GHz methanol masers being discovered in our Milky Way Galaxy. However, with the technological upgrades to the VLA (Perley et al. 2011), the methanol data from the GLOSTAR survey provides the most sensitive and unbiased catalogue to date.

Here, we report on the detection of 554 6.7 GHz methanol masers in the region of $l = -2^\circ$ to 60° and $|b| \leq 1^\circ$ (see Fig. 1 for survey coverage), with 84 of these representing new detections. We used an automated search algorithm to search and verify all detections manually. We looked for associations at other wavelengths to identify the physical properties of the population of sources with detected maser emission and the differences in these properties for newly detected sources with respect to the total population.

In addition to the part of the Galactic plane listed above, the Cygnus X star formation complex was also covered by the GLOSTAR survey. The 6.7 GHz methanol maser content of Cygnus X was discussed in a recent article by Ortiz-León et al. (2021).

We structure this paper as follows: in Sect. 2, we give a summary of the data used in this paper along with its calibration and imaging. Section 3 describes the algorithm used to detect masers in the VLA data. Section 4 details the production of our methanol maser catalogue and their general properties. Section 5 discusses our comparison with other surveys and associations with other wavelengths. We present our conclusions and summary in Sect. 6.

2. Observations

The GLOSTAR survey (Medina et al. 2019; Brunthaler et al. 2021) is an ongoing survey with the VLA and the Effelsberg 100 m telescope between 4–8 GHz of the Galactic mid-plane, from $-2^\circ < l < 60^\circ$ and $|b| < 1^\circ$, and the Cygnus X star-forming complex. The VLA observations used in this work were conducted in D-configuration with a typical angular resolution of $18''$ at 6.7 GHz. Using methanol, formaldehyde, and radio recombination lines as well as radio continuum data, the survey aims to detect various tracers of different stages of early star formation in order to gain information on the start of the stellar evolution process of massive stars. The full details can be found in Brunthaler et al. (2021). The observations used in this work were carried out using ~ 300 h during the time period from December 2011 until April 2017, where the program IDs and details are summarised in Table 1. Observations that were

Notes. ^(a)These observations were conducted with the VLA in DnC configuration.

Fig. 1. Methanol maser detections plotted as white crosses on top of the D-configuration continuum images from GLOSTAR where the flux has been limited to be between 0.2 and 2 mJy beam⁻¹ for visibility. The red “x”s show the positions of all new methanol masers as discussed in Sect. 4.5.

performed in the DnC hybrid configuration are marked in the table.

2.1. VLA data calibration

As detailed in Brunthaler et al. (2021), a modified version of the VLA scripted pipeline¹ (version 1.3.8) for CASA² (version 4.6.0) was adapted to work with spectral line data. We highlight the relevant changes here: no Hanning smoothing was performed on the first pass when producing the preliminary images to preserve the spectral resolution where possible; Hanning smoothing was performed on a select few sources after an initial inspection; the `rflag` flagging command was only applied to the calibration scans to avoid flagging spectral lines erroneously; `statwt` was not used to modify the statistical weights. The complex gain calibrators used for different fields include: J1804+0101, J1820-2528, J1811-2055, J1825-0737, J1907+0127, J1955+1530, J1925+2106, and J1931+2243, and the flux calibrators are 3C 286 and 3C48.

2.2. Spectral line data imaging

To process the spectral line data, we imaged it in two steps. We first produced a so-called “dirty” image (or unCLEANed), which is simply the direct Fourier transform of the uv data with the `tclean` task in CASA. We search these cubes for preliminary sources. We then properly carried out a CLEAN process on smaller sub-cubes centred on these sources to search for additional sources. This approach was chosen to address the computation limitations imposed by the sheer volume of data used. With the available computing resources at the time, it would take a month to produce a $2^\circ \times 1^\circ$ CLEANed data cube for the methanol data, where a dirty image would take only three days.

2.2.1. Imaging “dirty” cubes

Using the CASA task `tclean`, we were able to produce preliminary, mosaicked, and primary beam corrected images with the following task parameters: `niter=0`, a cube size (`imsize`) of 2500×2500 pixels, and a pixel size (`cell`) of $2.5''$ for the D-configuration data. The number of channels (`nchan`) and the rest frequency (`restfreq`) were set to 1800 channels and 6668.518 MHz, respectively. We used a “natural” weighting parameter for better sensitivity in detecting sources. On average, the 1σ root-mean-square (rms) noise in the line free channels of the dirty cubes is found to be ~ 18 mJy beam⁻¹ for a single channel (0.18 km s⁻¹), which is better than the estimated noise for a single pointing of ~ 40 mJy beam⁻¹ based on a 15-s integration time. This is due to the mapping strategy where each field has been overlapped by six neighbouring fields, resulting in sensitivities that are at least a factor of two better. The achieved sensitivity is about a factor of 2 better than previous VLA targeted surveys (e.g. Hu et al. 2016). We were able to detect weak and isolated masers in the “dirty” image itself, which contributes to savings in computational time. Weak masers that are in the vicinity of strong masers and with similar velocity may be missed, but will be found in the next stage of our imaging approach.

2.2.2. Imaging of individual masers

In order to find weaker masers that are hidden in the side lobes of stronger masers, we used the CLEAN algorithm on small subsets

of the data. We selected, on average, 16 pointings that cover the positions of sources detected from the “dirty” images. They were split out for further imaging and deconvolution to make smaller cubes ($\sim 0.2^\circ \times 0.2^\circ$, $\Delta v \sim 55$ km s⁻¹). These sub-cubes were then imaged with a cell (pixel) size of $2.5''$ and the imaging was restricted to the velocity ranges over which significant signal was detected. The sub-cubes have a spatial extent of 350×350 pixels and spectral extents of 300 channels centred on the peak velocity. Included at the beginning and end of the 300 channels, there are line free channels to estimate the spectral noise. For deconvolution, a CLEANing threshold of 38 mJy beam⁻¹ was chosen ($\sim 2\sigma$ of final cubes). Using the `tclean` task of CASA (version 5.4.0), the images were made with parameters: `gridded=“mosaic”`, `deconvolver=“hogbom”`, `weighting=“uniform”`, and a variable `niter`. The number of minor CLEAN cycles was set to either 1000, 5000 or 10 000 depending on the strength of the maser involved. These iteration values were found to optimize the automatic cleaning for many sources by maximizing image fidelity while avoiding over-cleaning. The weighting parameter was set to “uniform,” since it gives a better angular resolution and thus more accurate positional information.

2.3. Complementary continuum data

In addition to the methanol line data, we also used GLOSTAR-VLA radio 5.8 GHz continuum data to search for associations with methanol masers. Radio sources such as ultra-compact HII regions (UCHII) are a clear indicator of HMSF, however, their relationship with methanol masers is not yet fully understood. Thus, a study of the associations and the physical properties of these sources may give valuable insights into the overall formation process of high-mass stars in this stage of their evolution. The full analysis of continuum maps in the D-configuration and B-configuration will be presented in forthcoming papers (Medina et al., in prep; Dzib et al., in prep.; Yang et al., in prep.), while the D-configuration continuum catalogue for the pilot region is already complete (Medina et al. 2019). We also make use of the Co-Ordinated Radio “N” Infrared Survey for High-mass star formation (CORNISH, Hoare et al. 2012; Purcell et al. 2013), which uses the VLA in the B and BnA-configuration at 5 GHz, to supplement our comparisons.

3. Source extraction

Here we give a technical description of the algorithm used for automatically selecting maser candidates from the “dirty” images. A description of the final catalogue is given in Sect. 4.1.

3.1. Source extraction code

As explained in Sect. 2.2, given the computational challenge of imaging and deconvolving large mosaics, we adopted an approach of searching for the methanol masers in the dirty images. We wrote a simple source extraction code (SEC; Murugesan 2015; Nguyen 2015) to deal specifically with this data in a rapid manner. This SEC was written to detect methanol masers that have high brightness values in comparison to the surrounding noise. It was also adapted for absorption searches (see Brunthaler et al. 2021). It takes the “dirty” or fully CLEANed images as input. The code was first used on the “dirty” images to produce a preliminary catalogue of detections which were verified by visual inspection. The verified detections were CLEANed over a small spatial and spectral extent (see Sect. 2.2.2). The code

¹ <https://science.nrao.edu/facilities/vla/data-processing/pipeline/scripted-pipeline>

² <https://casa.nrao.edu/>

was then used again on these sub-cubes to find any other masers that were previously not detected on account of their proximity to stronger sources.

The code scans through the images, saving the coordinates where the brightness meets two criteria. The first and foremost is that the emission surpasses a certain signal-to-noise ratio (S/N) threshold. Secondly, we require that the emission is above this threshold for at least two consecutive channels. If these two criteria are satisfied, the code considers such a detection as real.

We selected a 50×50 pixel “box” to start. Beginning from the first channel, the root mean square (rms) of the box is calculated by the code. This is then chosen to be the noise within the box. Next, the code selects the pixel with the maximum flux. The ratio between the maximum flux and the rms of the box then defines the S/N. This is done iteratively for each channel within the boundaries of the 50×50 pixel box for the entire spectral extent of the given image. For a given channel, where the S/N is above a user-defined threshold, we check if it continues for at least another contiguous channel in order to satisfy our main criteria described above. If it also passes through three additional selection filters (defined below), it qualifies as a potential source. We then record the pixel coordinates, right ascension (RA), declination (DEC), channel range, peak flux, the associated channel of the peak flux, and the S/N. The code moves onto the next spatial box and repeats the search along the spectral axis. After its completion, a catalogue of the potential sources is produced. As a final check, we always verify each source visually. A flow diagram illustrating the algorithm is presented in the top of Fig. 2 and an illustration of the physical movements of the search algorithm is shown in the bottom. In order to reduce false detections and repeated detections, we describe the aforementioned filters used to improve the quality of detections:

First filter (F1). This filter checks if the current potential detection is within 200 pixels from the previous detection and also appears in the same channel range. If these conditions are met, it checks if the S/N of current detection is greater than the previous detection. If this is the case, the current detection is updated as the true detection and its coordinates kept as a reference.

Second filter (F2). The next filter checks if the current detection is within 200 pixels of the previous detection, but appears in a different channel range. Since side lobe artefacts appear in the same channel range as the source, we consider the detection a potential source if the channel ranges are different. This helps to differentiate multiple sources within the same box.

Third filter (F3). The final filter checks if the current detection is more than 200 pixels away from any previous detection. An angular separation of 200 pixels ($\sim 8.3''$) is chosen as typically this is the largest extent of any side lobe feature. If this criterion is met, the code selects the pixel as a potential source.

We chose a S/N value of 6 when searching through the “dirty” images. This choice is based on the general statistics of the cube in order to balance dismissing artefacts as well as picking up weak sources. For the CLEANed sub-cubes, we used a lower S/N value of 4 as it was found to be the most efficient in detecting the generally weaker sources that were initially hidden in the side lobes of the nearby stronger sources.

Since the algorithm picks out just one maximum in a given box, it is possible that real but weaker sources are missed if they lie in the same box. It was found that a box size of 50 pixels (corresponding to $\sim 2''$; in comparison, the primary beam of the VLA at 6.7 GHz is $6.5''$) substantially minimizes the run time without

Fig. 2. Algorithm flow chart for the Source Extraction Code (SEC) which details the selection of the positions and channels of maser candidates based on the signal-to-noise ratio S/N (top panel; for details, see Sect. 3). Illustration of the process used by the SEC (bottom panel). A 50×50 pixel box that starts from the bottom left corner (BLC) iterates first through channels to detect sources until it reaches the top right corner (TRC).

losing too many additional sources. Furthermore, because we are using a “dirty” image, there are noisy structures in the neighbourhood of strong sources. In the direct vicinity of a potential strong source, the code will reliably pick out the pixel coordinates of the real source as side lobe features will never have a higher flux than the actual source. The spillage of side lobe features into adjacent boxes is mitigated by the utilisation of the filters defined above.

Given the simple nature of the algorithm, the code can be easily parallelized. The parallelization is done by splitting the

Fig. 3. Example of the Source Extraction Code (SEC) on unCLEANed and CLEANed data sub-cubes. *Left:* example peak intensity map of a dirty sub-cube towards $l = 26.5270$ deg, $b = -0.2674$ deg which is an example of the data used when making preliminary detection catalogues with our SEC. Velocities of known sources are shown in red text, while pink squares highlight the final source detections. In this “dirty” image, the bottom two sources would not have been detected. *Right:* once we CLEAN the image, we can see how the two bottom sources would indeed be detected by our SEC and, as such, illustrates how running the SEC again on the cleaned sub-cubes can lead to new detections.

spatial extent of the image into smaller patches. The code is then run individually on each of these patches. Each process creates its own search catalogue, which is then combined when all processes are finished. For a strong source, side lobe artefacts can spill over onto the next patch and be picked up in a different catalogue. We resolve this through a visual verification.

3.2. Catalogue creation

After performing the initial pass with the SEC on the “dirty” images, we carried out a cross-check with all known masers in the survey range in case there are weaker known sources that do not pass our initial noise threshold criterion. We further inspected all the potential SEC detections, looking at their spectra and moment maps. We examined the positions, velocities, and intensities of the detections to decide which SEC candidates are to be considered real. We visually checked for any velocity features that have very large offsets from other velocity features along the line of sight to also be considered as a new maser. From this, we compile a list of candidates for further cleaning.

For these maser candidates, we made smaller CLEAN images (as described in Sect. 2.2). We ran our SEC code with modified settings (box size of 5 pixels and no filters) in order to pick up weaker sources that would have been hidden by a nearby strong source. We visually inspected each cube at the end to ensure that we picked up all possible masers in the data. In Fig. 3, we give an example of two new methanol maser detections that were not found in the ‘dirty’ image cube due to the presence of nearby strong sources.

From this final visual inspection, we compiled a final list of detections. As we were interested in determining the methanol masers’ properties, we performed a 2D Gaussian fit of the brightness distribution in each channel whose peak intensity is above 4σ . We used the CASA task `imfit` on a 14×14 pixel box ($\sim 2\times$ the restoring beam), which is centred on the pixel with maximum intensity. As discussed in Ortiz-León et al. (2021), the error

in maser position is determined by the astrometric uncertainty $\theta_{\text{res}}/(2\times\text{S/N})$, where θ_{res} is the (VLA) restoring beam, and S/N is the ratio between source intensity and rms (Thompson et al. 2017). Given that the average beam size in the D-configuration methanol maps across the whole Galactic plane is $15''$, and a maser detection with S/N=10, the precision in position is $\approx 0''.7$. We further discuss the reliability of our position measurements in Sect. 4.5. We visually verified the result of the source fits and determined the peaks of each maser site. We refer to each velocity peak as a maser spot inside one maser site (Walsh et al. 2014). A few examples of these, including new maser sites, are listed in Table 2, while the complete catalogue can be found at the CDS. The positions for all emission channels of a given maser site are given as an offset to the position of the maser spot with the strongest emission within the maser site.

4. Results

4.1. Detections

We detected a total of 554 CH_3OH maser emission and 6 cases of methanol absorption in the range of GLOSTAR survey coverage ($-2^\circ < l < 60^\circ$, $|b| \leq 1^\circ$; see Ortiz-León et al. 2021 for the 13 masers found in the Cygnus X region, or the CDS table for all 567 GLOSTAR masers). Of these detections, we have determined 84 ($\sim 15\%$) of them to be new detections. As we require that for a source to be detected, a minimum of two adjacent channels must meet our S/N threshold, our estimated completeness level may be higher than the 4σ noise level. We overlay the detections on top of the GLOSTAR D-configuration continuum emission in Fig. 1 and display their spatial distributions in Figs. 4 and 5. We note that within the GLOSTAR Galactic longitude range, the CH_3OH 6.7 GHz maser source distribution seems to peak towards $l = 30^\circ$, which is not surprising given the multiple crossings of spiral arms of the Milky Way, as is evident from Fig. 6. The distribution in Galactic latitude is presented in Fig. 5, which shows that the majority of sources are in the range of $|b| \leq 0.5^\circ$.

Notes. Column (1) gives the GLOSTAR source name based on the GLOSTAR Galactic coordinates. Columns (2) and (3) are the GLOSTAR equatorial coordinates of the position of the maser velocity component with the highest intensity. For sources with multiple components, we list their position offsets with respect to the component with the highest intensity. The position uncertainties are $\sim 1.1''$ (see Sect. 4.5). Column (4) gives the LSR radial velocity of the peak of the component. Columns (5) and (6) give the peak and integrated fluxes at the peak velocity, given by Col. (4). Column (7): Source references.

Fig. 4. Distribution of detected masers along Galactic longitude. The bin width used is 5° from $l = 60^\circ$ to 0° and 2° for the last bin.

Fig. 5. Distribution of detected masers along Galactic latitude. The bin width used is 0.08° .

Fig. 6. Distribution of detected 6.7 GHz methanol maser velocity with respect to Galactic longitude. Black crosses represent detections of known sources in the GLOSTAR survey and red crosses represent new detections. The coloured spiral arms are as follows: magenta is 3 kpc, red is Norma-Outer, blue is Scutum Centaurus, green is Sagittarius Carina, and yellow is Perseus. The dashed lines represent the updated spiral arm models of Taylor & Cordes (1993) as used in, e.g. Schuller et al. (2021) while the solid lines are the spiral arm descriptions from Reid et al. (2019). The background shows the CO emission from Dame et al. (2001).

The properties of a few example detections are listed in Table 2, and we refer to the catalogue at the CDS for the full list of detections. We identify each maser source by its galactic coordinates. The equatorial coordinates for the maser spot with the highest peak flux, which is the main velocity component, is given while the remaining maser spots (if any) are given as an offset to this main maser spot. The velocity of each maser spot as well as its peak flux and integrated flux are listed in the table. The fluxes were determined using 2D Gaussian fitting (see Sect. 3.2). Additionally, we report in the online catalogues every velocity channel where emission was detected above the 4σ level for a given maser.

4.2. Flux densities

The brightest 6.7 GHz CH_3OH maser that we detected is the well-known example of G9.6213+0.1961, with a peak flux density of ~ 5700 Jy. This source is known not only as the methanol maser that reaches the highest flux density, but also, given its distance of 5.2 kpc, it has the highest line luminosity (Sanna et al. 2015). Conversely, the weakest maser we detect is the source G25.1772+0.2111 with a peak flux density of ~ 0.09 Jy. For the newly detected masers, the fluxes range from 0.16 Jy to 5.4 Jy. The median peak flux density of the newly detected masers is 0.47 Jy. The surface density of new detections across the survey coverage is ~ 0.8 masers per sq. degree. We detected a total of 80 masers above 20 Jy, none of which are new detections.

4.3. Distance determination

To calculate the luminosity of a maser source, the distance information is required. This can be obtained from the peak velocity of the maser and comparing it to a Galactic rotation curve.

However, there is an inherent kinematic distance ambiguity that affects all sources within the Solar Circle (see Roman-Duval et al. 2009 for an overview). To resolve this, we used the distances obtained from associated ATLASGAL 870 μm emission sources (Schuller et al. 2009) from the compact source catalogue (Urquhart et al. 2018, 2022) as they have been individually checked for HI self-absorption. However, not every maser source has a dust clump association from ATLASGAL and in these cases, we used the Bayesian distance estimator from Reid et al. (2019) to help resolve the kinematic distance ambiguity. We show the distribution of our maser sample overlaid on an artist's impression of the Milky Way³ in Fig. 7. We note that this method is biased to the location of the spiral arms, which can be seen by its very smooth distribution along curves.

4.4. Luminosity

The luminosity is estimated across all the velocity channels in which we have emission of $>4\sigma$. In this way, we used the line flux, that is, the velocity integrated flux density, S_{Int} in units of Jy km s^{-1} to determine the luminosity:

$$L_{\text{maser}} = 4\pi D^2 S_{\text{Int}} f / c, \quad (1)$$

where D is the heliocentric distance to the source, f is the rest frequency of the maser line ($5_1 - 6_0\text{A}^+$, 6668.5192 MHz), and c is the speed of light. The total velocity covered, ΔV_D , the estimated distance, the velocity integrated flux density, S_{Int} , and the final isotropic maser luminosity, L_{maser} , are listed for a few example sources in Table 3 and the rest are listed in a catalogue at the CDS. As mentioned by previous studies (Breen et al. 2011; Billington et al. 2019; Ortiz-León et al. 2021), a positive trend

Notes. Refer to the online table for a complete list of sources. Column (1) is the GLOSTAR source name. Column (2) gives the total velocity extent of maser emission above the local 4σ level. Column (3) gives the distance obtained from the Bayesian distance estimator (Reid et al. 2019) or from the ATLASGAL compact source catalogue (CSC) (Urquhart et al. 2018, 2022) as marked in Col. (4) with a B or A respectively. Columns (5) and (6) give the maser integrated flux and luminosity, respectively.

Fig. 7. Distances of 6.7 GHz methanol masers from GLOSTAR D-configuration VLA observations plotted on top an artist's rendition of the Milky Way. We used the distance estimator (Reid et al. 2019) to assign the near or far distance to a source (red stars) except for maser sources with an ATLASGAL dust clump association, for which we used the reported distance from Urquhart et al. (2018, 2022), shown as a green triangle.

between the total velocity width, ΔV_D , of a maser source and its maser luminosity is shown in Fig. 8. Given that we can take the velocity range of a maser as a proxy for line complexity, that is, for many components, it might naively be expected that stronger sources are more complex. However, it could also be that for weaker sources, there may be other velocity components, however, if these components do not meet the S/N threshold, they are thus not considered. We have fit a power law in the form of $\Delta V_D \propto L_{\text{maser}}^\alpha$ to the relation and found $\alpha = 0.32 \pm 0.01$,

Fig. 8. Total velocity range of maser emission vs. integrated maser luminosity as blue crosses. Here, we see a positive trend. The green line represents a power law fit to the data with an exponent of 0.32 ± 0.01 . A Spearman correlation test yields a rank coefficient of $r = 0.74$ and p -value $\ll 0.0013$, which indicates a positive correlation and is consistent with previous studies using a smaller sample (e.g. Ortiz-León et al. 2021).

which supports the positive trend we see (a Spearman correlation test yields a coefficient $r = 0.74$ and p -value $\ll 0.0013$, which strongly supports the correlation).

4.5. Comparison with other maser surveys

The Arecibo Methanol Maser Galactic Plane Survey (AMMGPS, Pandian et al. 2007), using the 305 m Arecibo radio telescope to cover the ranges of $35.2^\circ \leq l \leq 53.7^\circ$ and $|b| \leq 0.41^\circ$, detected 86 masers. The survey has an rms noise level of ~ 85 mJy in each spectral channel after Hanning smoothing and averaging both polarizations. Of these masers, only G35.374+0.018 at 96.9 km s⁻¹ and G36.952–0.245 at 61.7 km s⁻¹ were not detected by our survey. This may be due to the time variability of methanol masers, making these sources candidates for long term observations.

The Methanol Multibeam (MMB) survey (Green et al. 2009) is a comprehensive, unbiased survey that covers a large portion of the Galactic plane, ranging from $186^\circ \leq l \leq 60^\circ$ and $|b| < 2^\circ$.

Fig. 9. Comparison of the positions of matching MMB and GLOSTAR methanol maser sources. The red shaded ellipse is centred on the mean offsets of $\delta l = -0.18$ arcsec, and $\delta b = 0.04$ arcsec. It shows the half-axis standard deviations in Galactic Longitude and Latitude, which are 1.21 arcsec and 1.03 arcsec, respectively.

It uses the Parkes 64 m radio telescope to make preliminary detections which are followed up on using the higher resolution interferometers: Australia Telescope Compact Array (ATCA) or Multi-Element Radio Linked Interferometer Network (MERLIN, Thomasson 1986) to improve the accuracy in their reported positions to be better than $<1''$. The survey sensitivity is ~ 0.2 Jy. Of the ~ 1000 sources in their complete catalogue (Caswell et al. 2010, 2011; Green et al. 2010, 2012; Breen et al. 2015), 404 lie within the GLOSTAR data presented here. Of these, 394 were detected in our survey. As GLOSTAR is an unbiased survey, it is useful to compare the catalogues resulting from these surveys.

To augment our comparison, we also used the Yang et al. (2019b) catalogue of 6.7 GHz CH_3OH masers that were obtained through a targeted search towards sources from the Wide Field Infrared Survey Explorer (WISE) point source catalogue using the 65 m Shanghai Tianama Radio Telescope (TMRT). These surveys were used to help in the identification of our SEC detections (presented in Sect. 3) where weak sources that were close to the 4σ threshold were conclusively kept as a detection given matching coordinates and velocities. This resulted in 113 detections that were not detected by Yang et al. (2019b). There are some masers from Yang et al. (2019b) that were undetected in the GLOSTAR survey, with the majority having fluxes below our sensitivity limit. While the sensitivity of the observations done by Yang et al. (2019b) with the TMRT is 1.5 Jy K^{-1} , their catalogue also includes weaker masers that were previously included in the literature.

We carried out a final check with the webtool, Maserdb⁴ (Ladeyschikov et al. 2019), which is an online collection of catalogues of many maser species (e.g. OH, H_2O). We find that our catalogue has 84 new 6.7 GHz CH_3OH maser emission sources (see Fig. 1).

Next, we compared the GLOSTAR and the MMB positions. In Fig. 9, we show the position offsets to the GLOSTAR

Fig. 10. Flux distribution of detected masers. The vertical dashed red line corresponds to the average 4σ noise level for the methanol D-configuration data ($\sim 70 \text{ mJy beam}^{-1}$). We show the full set of GLOSTAR fluxes, as well as the subset with MMB associations, and all new detections. As expected, the bulk of the new detections peaks at lower flux densities.

D-configuration detections. The mean offsets are $\delta l = -0.18 \pm 1.21$ arcsec and $\delta b = 0.04 \pm 1.03$ arcsec. This indicates that there are no systematic offsets in the astrometry with respect to the MMB catalogue. However, the standard deviation of the offsets suggests that the astrometric uncertainty is closer to ~ 1.1 arcseconds, which is slightly higher than the statistical uncertainties of $0.7''$ determined for a 10σ detection.

We show in Fig. 10 the flux distributions of the GLOSTAR methanol maser detections. We highlight the subset of sources that have a MMB counterpart as well as the subset of new sources. In comparison with the MMB catalogue, we directly see that our increased sensitivity finds new, weaker sources. However, there are 74 sources above the survey cube detection threshold of 0.7 Jy that we would have expected to be detected by the MMB. There are several possible reasons for this. Given that these observations were taken years apart, it could be the result of variability, making these sources possible candidates for long term observations. Furthermore, close to 30 of these sources are situated near bright sources and as such, they were not able to be initially resolved by the MMB in their blind survey. Examples of these are shown in Appendix A.

For masers with counterparts in both surveys, we compared the peak fluxes in Fig. 11. The fluxes do not show a systematic difference. G9.6211+0.1956 is already known to be a periodic Class II CH_3OH maser with a period of ~ 244 days (e.g. Goedhart et al. 2007; van der Walt et al. 2009)⁵. We detected two main velocity components for this source at the known velocity of 1.3 km s^{-1} and at a new velocity of -88.7 km s^{-1} . Given the large difference in velocity, we consider these to be distinct entries in our catalogue. Both of these spatially coincide with the known MMB maser at the same position. The component at 1.3 km s^{-1} has a high peak flux density of $>5700 \text{ Jy beam}^{-1}$ in both the GLOSTAR and the MMB

⁵ In periodic methanol masers, certain velocity components show periodic variability with a wide range of periods, ranging from 20 to >500 days. As discussed in a future publication, the several epochs at which the GLOSTAR data were taken and comparison with MMB spectra will lead to the detection of new candidates of these interesting sources (e.g. Goedhart et al. 2018, and references therein).

⁴ maserdb.net

Fig. 11. Comparison of GLOSTAR vs. MMB peak flux densities for masers detected in both surveys. The black line indicates the 1:1 equality line. Red circles denote sources for which the percent difference was greater than 50%.

Fig. 12. Flux distribution of masers as reported in the GLOSTAR, the MMB (Green et al. 2009) and the Yang et al. (2019b) catalogues. The vertical dashed red line corresponds to the average 4σ noise level for the GLOSTAR methanol D-configuration data (~ 70 mJy beam $^{-1}$). The sources of the other surveys that were not detected in the GLOSTAR survey are well below the sensitivity level of our unbiased search.

spectra with a matching velocity, which corresponds to the velocity of the host source. As such we consider this the true association for the following analysis. The component at the velocity of -88.7 km s $^{-1}$ is much weaker with a peak flux density ~ 1 Jy beam $^{-1}$. Emission at this velocity seems to not yet have been detected towards this source and deserves further study.

In Fig. 12, we compare the flux distributions between the GLOSTAR, MMB, and Yang et al. (2019b) catalogues for masers within the GLOSTAR survey coverage. It is evident that there are masers below our detection threshold that were not detected. The detection comparison between the three maser surveys is shown in Fig. 13 and details how many masers have been detected by each survey and their overlap. There are 44 sources that we did not detect, but that were detected by Yang et al. (2019b) or by both Yang et al. (2019b) and the MMB. Of these, 14 have reported fluxes below our sensitivity limit. Variability may also

Fig. 13. Venn diagram presenting the overlap between the GLOSTAR methanol maser catalogue, the MMB (Green et al. 2009) and the Yang et al. (2019b) catalogues over the same region as GLOSTAR. We detected 112 masers that had not been detected by the MMB or the Yang et al. (2019b) catalogues, while we did not detect 44 known masers.

account for some of the other non-detections, however, long term observations would be needed to confirm this nature of maser activity. We also see that while there are some known masers that we do not detect, the majority of our new detections are in the lower flux bins as expected.

4.6. Absorption detections

While detections of the 6.7 GHz $5_1 - 6_0 A^+$ CH $_3$ OH line are widespread, the absorption detections are comparatively more sparse. Only a few studies have confirmed the 6.7 GHz line in absorption thus far (e.g. Menten 1991b; Pandian et al. 2008; Impellizzeri et al. 2008; Ortiz-León et al. 2021; Yang et al. 2022). Absorption in this line can occur towards radio continuum emission and the cosmic microwave background (CMB). In conjunction with maser emission detections, we are also sensitive enough to detect absorption features and indeed we find a few absorption sources (listed in Table 4), where an example is shown in Fig. 14. A systematic search had not yet been performed and thus a comprehensive list of all absorption detections is not presented in this work. An in-depth analysis of the absorption sources detected in the GLOSTAR data will be performed in a future work, for which we will use the complete GLOSTAR D-configuration continuum source catalogue (Medina et al., in prep.) to check for methanol in absorption.

5. Discussion

5.1. Association with ATLASGAL sources

Methanol masers are known tracers of star formation and the Class II 6.7 GHz methanol maser is thought to exclusively trace the early stages of HMSF (Minier et al. 2003; Ellingsen 2006; Xu et al. 2008). Recently, Billington et al. (2019) used the MMB and ATLASGAL surveys to do a comprehensive study on the physical environments of the regions these masers originate from. They used newly available distances and luminosities to compare with the clump properties as determined in ATLASGAL and JPS

Table 4. Examples of absorption features detected.

Common name	α (h:m:s)	δ (d:m:s)	v_{Peak} (km s ⁻¹)	S_{Peak} (Jy beam ⁻¹)
Sgr B2	17:47:18.71	-28:22:53.54	70.4	-2.0

W49	19:10:12.97	09:06:10.98	12.55	-0.3

Notes. The source is listed with equatorial coordinates (J2000), the peak velocity feature, and the peak flux density.

Fig. 14. CH₃OH 6.7 GHz spectra of the maser source G0.677-0.025 near Sagittarius B2. Broad absorption can be seen between the velocity range of 50 km s⁻¹ and 90 km s⁻¹.

(JCMT Plane Survey: Moore et al. 2015; Eden et al. 2017) to determine correlations for maser associated sources. As seen in previous studies (e.g. Urquhart et al. 2013, 2015; Billington et al. 2019), there is a ubiquitous association with the MMB masers and dust continuum sources (99%), strongly correlating these masers with the earlier stages of HMSF. Billington et al. (2019) determined that values of clump masses and radii are not indicative of a clump having a 6.7 GHz methanol maser, whereas the measurement of clump density may be able to make this indication. Furthermore, these authors determined a lower density threshold of $n(\text{H}_2) \geq 10^{4.1} \text{ cm}^{-3}$ for the “turning on” of maser emission. As such, with our sample, especially our new weaker detections, it is interesting to see whether these correlations hold.

We performed a cross-matching with ATLASGAL sources using an emission map and distance threshold of 12'', which is three times the pointing uncertainty of ATLASGAL and was determined from analysing the surface density distribution of matches. We use the ATLASGAL CSC from $l = 3^\circ$ to 60° as the source properties for sources in the region of the Galactic centre are not at the same confidence level. We find 363 associations within 12'' (~65%) between GLOSTAR masers and the ATLASGAL compact source catalogue (CSC; Urquhart et al. 2018, 2022) for which the dust clump properties (e.g. clump mass, clump temperature, bolometric luminosity) were calculated. The ~65% association with dust emission is lower than

Fig. 15. CH₃OH 6.7 GHz maser peak flux density compared to 870 μm dust emission extracted from ATLASGAL maps towards the maser position. Black crosses correspond to sources that were matched to the ATLASGAL compact source catalogue (CSC). The remaining sources are marked in blue. The red dashed line corresponds to the ATLASGAL 6σ noise level and the red circles highlight the new masers found in this work.

expected from the studies mentioned above. For masers without an ATLASGAL CSC association, it is possible that they are still associated with dust as they could be associated with more distant clumps well below the ATLASGAL threshold. They could also be situated at a closer heliocentric distance to us, but are instead associated with low-mass clumps.

To address this discrepancy, we visually inspected ATLASGAL cutouts centred on the positions of the masers (examples can be found in Appendix B), using dust continuum contours from 1σ to 5σ . We took this approach as the ATLASGAL CSC uses a threshold of at least 6σ for the sources they report, but there are still many potential dust continuum sources below this limit. In this way, we find that there are an additional 72 maser sources that show compact dust emission above 3σ . There are a further 93 maser sources that can be associated to an extended ATLASGAL feature above 6σ and 7 maser sources that are offset slightly further than 12''. As such, we find that only 18 maser sources have no dust continuum emission, which corresponds to a methanol maser and dust continuum association of ~97%. The result is in agreement with previous studies (e.g. Billington et al. 2019). From Fig. 15, we find that there seems to be a cluster of new maser detections that are centred on the lower end of the dust emission around the 6σ noise level of ATLASGAL.

We compare the velocities of the maser’s median velocity and the velocities of the matched dust clumps in Fig. 16. The ATLASGAL velocities were assigned by matching clump positions with observations of molecular line transitions from multiple molecular line surveys (see Urquhart et al. 2018, Sect. 2.1 for details). A linear fit yields a slope and y -intercept of 1.00 ± 0.13 and 0.01 ± 0.75 , respectively, and with Spearman’s rank coefficient of $r = 0.98$ and p -value $\ll 0.0013$ supporting the positive correlation. In fitting a Gaussian to the distribution of the velocity offsets, we find a mean offset of $0.49 \pm 0.18 \text{ km s}^{-1}$ and dispersion of $3.69 \pm 0.1 \text{ km s}^{-1}$. The result is in agreement with the results from Billington et al. (2019), who compared the total MMB sample with corresponding ATLASGAL sources, where they used sources with offsets of $<3\sigma$. There are three sources, however, with

Fig. 16. Comparison of the velocities of the methanol masers and their associated dust clumps. *Left:* the median methanol maser velocity plotted as a function of the ATLASGAL clump velocity for sources with an association to an ATLASGAL compact source catalogue (CSC) source. The black line is the fitted linear result, with a Spearman’s rank coefficient of $r = 0.98$ and p -value $\ll 0.0013$. *Right:* distribution of the offsets between the median methanol maser velocities and the molecular line velocities from ATLASGAL. Fitting the distribution with a Gaussian yields a mean of 0.49 ± 0.18 km s⁻¹ and standard deviation of 3.69 ± 0.1 km s⁻¹. We use 3σ (11 km s⁻¹) as a confidence threshold to identify outliers.

greater velocity offsets: G3.5022–0.2005, G9.6211+0.1956, and G10.3563–0.1484. These were all previously detected in the MMB, with G3.5022–0.2005 being associated with millimetre dust continuum (Rosolowsky et al. 2010) and G10.3563–0.1484 associated with a YSO candidate (Deharveng et al. 2015). G9.6211+0.1956 is associated with the well-studied HII region of similar name, where its shock fronts have been studied (e.g. Liu et al. 2017, and references therein). As mentioned in Sect. 4.5, there are two sources in our catalogue with vastly different velocities associated with this ATLASGAL source. The maser at 1.3 km s⁻¹ is consistent with the well-studied clump velocity. This other velocity component at -88.7 km s⁻¹ would be an interesting target for future studies.

We show the cumulative distribution functions (CDFs) of the clumps associated with GLOSTAR masers and clumps associated with just the new detections in Fig. 17 for different associated clump properties such as dust temperature, bolometric luminosity, clump mass, luminosity to mass ratio, clump size, and H₂ density. A comparison of a sample of 364 maser associated clumps with that of 45 clumps associated with newly detected GLOSTAR masers. Urquhart et al. (2022) shows CDFs (in their Fig. 7) that compares the clump properties for different evolutionary stages of ATLASGAL sources, indeed demonstrating that it is possible to distinguish evolutionary stages on the basis of certain properties. Furthermore, Billington et al. (2019) compared the properties of ATLASGAL clumps with the subset that have MMB methanol maser associations. They found that maser associated sources have higher dust temperatures, bolometric luminosities, and luminosity-to-mass ratios, which is expected as these are regions in the process of developing high-mass stars (see Fig. 10 from Billington et al. 2019). In contrast to these works, we investigate the ATLASGAL sample of sources that have GLOSTAR methanol maser associations with the subset of those that are newly detected masers. We perform Anderson-Darling tests for all CDFs instead of Kolmogorov–Smirnov tests as the Anderson-Darling test is more sensitive to changes at the boundaries, which is the subset of our sample that we are more interested in, given that most of our newly detected masers are weaker. The results are shown on the plots

in Fig. 17. Clump luminosity is the only statistically different sample to the 3σ level (p -value < 0.0013), while dust temperature and luminosity-to-mass ratio are significant only to the 2σ level (p -value < 0.05). In obtaining more clump properties for the masers without an ATLASGAL CSC counterpart, it will help improve the determination of the significance of the Anderson-Darling tests on these properties. Furthermore, we see that for the dust temperature, bolometric luminosity of the clump, and luminosity-to-mass ratio, the mean properties for the new maser detections are slightly lower, but they do extend to similar limits on the high end as the general population of masers. It is reasonable to naively expect this as lower luminosity masers may trace earlier stages of development.

We also compare the 6.7 GHz methanol maser luminosity to the dust clump properties of luminosity and mass in the left and middle panels of Fig. 18. To test whether these two dust clump properties are correlated to the maser luminosity, we performed a Spearman’s rank correlation test that yields values of $r = 0.28$ and $r = 0.18$ respectively (with p -value $\ll 0.0013$) and so, there is a weak but significant correlation. The left panels of Fig. 18 shows the comparison between maser and clump luminosities and the distribution of the clump luminosities, where we have plotted (for reference) the dust core luminosity value of $\sim 200 L_{\odot}$ as found by Ortiz-León et al. (2021) to be the lower limit of methanol maser associated clumps in the Cygnus X region. There are a few sources in our sample that show luminosities lower than this. The sharp cut-off does lie, however, close to this value and not around $10^3 L_{\odot}$, as estimated by Bourke et al. (2005). Our results are in agreement with other recent studies such as Ortiz-León et al. (2021), who used similar data but for a small sample in the Cygnus X region, Paulson & Pandian (2020), who used a sample of 320 MMB masers, and Billington et al. (2019) who used a sample of 958 methanol masers from the MMB.

The middle panel in Fig. 18 similarly shows the investigation using the ATLASGAL full width at half maximum (FWHM) masses (mass within 50% of the 870 μ m contour) for the clumps. Ortiz-León et al. (2021) determined the minimum core mass in Cygnus X for maser associated cores to be $\sim 10 M_{\odot}$,

Fig. 17. CDFs for various properties of ATLASGAL clumps associated with GLOSTAR methanol masers. We compare the sample clumps associated with new methanol maser detections (red) to the sample of clumps with associations to the full methanol maser catalogue (blue). The results of the Anderson-Darling (AD) test are shown above each plot.

Fig. 18. Maser-integrated luminosity measured in D-configuration GLOSTAR data as a function of ATLASGAL clump properties shown in the *top row*: Bolometric luminosity (*left*), FWHM mass (*middle*), and luminosity-to-mass ratio (*right*). The black crosses represent masers with ATLASGAL compact source catalogue (CSC) counterparts, while the crosses surrounded by magenta circles highlight masers that were newly detected as part of the GLOSTAR survey. The *bottom row* shows the distribution of ATLASGAL molecular clump properties for the new masers (hatched green) in comparison to the full sample (yellow) of clumps associated with masers. The red-dashed lines denote the lower limits of the respective properties determined by [Ortiz-León et al. \(2021\)](#). The blue-dashed line denotes the upper bound at which maser emission is expected to decline due to the disruption of the physical conditions required for maser emission (e.g. expanding HII regions and dispersion of the host clump; [Walsh et al. 1997, 1998; van der Walt et al. 2003](#)).

while Billington et al. (2019) used the FWHM clump masses of the ATLASGAL sample to estimate a lower limit of $\sim 17 M_{\odot}$. Paulson & Pandian (2020) determined a value similar to that reported by Ortiz-León et al. (2021) of $11 M_{\odot}$ for their sample. These clump values are sufficient to produce high-mass stars if one assumes a 10% star formation efficiency. We used the FWHM clump masses of ATLASGAL and find a minimum mass of $0.175 M_{\odot}$. Rather than being the true lower limit, we see that it is likely an exception, since all but four data points have clump masses above the lower limit estimated by Ortiz-León et al. (2021). Since we use masses from the same sample as Billington et al. (2019), we similarly see a cut-off at around $\sim 17 M_{\odot}$ but the first percentile of the mass is $\sim 10 M_{\odot}$.

In combining the clump properties of luminosity and mass, the luminosity-to-mass ratio (L/M) has been shown to serve as a statistical indicator of the evolutionary stage of high-mass star forming clumps (Molinari et al. 2008). Furthermore, Billington et al. (2019) found a weak correlation between the L/M ratio of maser associated clumps and maser integrated luminosity. In the right part of Fig. 18, we find a Spearman's rank coefficient of $r = 0.3$ with p -value $\ll 0.0013$, which suggests that there is a weak correlation between the properties. We find that 90% of the data points lie between the values of $1 L_{\odot} M_{\odot}^{-1}$ and $10^{2.2} L_{\odot} M_{\odot}^{-1}$. These values estimate the lower and upper limits of the L/M ratio, which depict the onset of maser emission and the decline of the maser due to the formation of the HII region having disruptive effects on the maser's environment. Our results are in agreement with previous studies (e.g. Breen et al. 2010; Billington et al. 2019, 2020; Ortiz-León et al. 2021).

We also highlight the dust clumps that are associated with newly detected masers in Fig. 18. Contrary to our hypothesis that the newly detected and weak masers would strongly trace the earliest stages of high-mass star forming clumps, we see that except for clump luminosity, the histograms shown in Fig. 18 have similar shapes. Furthermore, the Anderson–Darling tests in Fig. 17, save for the bolometric luminosity, show no significant correlation between the samples to the 3σ level. We note that many newly detected masers have low maser luminosity ($< 10^{-6} L_{\odot}$) and the lack of a strong correlation of this sample is in agreement with Paulson & Pandian (2020); this suggests that other properties, such as gas density and gas temperature, are perhaps more important factors for the maser luminosity than the dust clump bolometric luminosity. However, there are some of new masers we report (53) that have ATLASGAL associations, but for which we do not have the clump properties and, as stated above, which are generally associated with lower 870 μm emission dust clumps. As this is a significant portion of our new detections, the outcome of the sample comparison presented here may differ once we obtain the host clump properties for these masers in future works. The results presented here are in agreement with previous results (e.g. Billington et al. 2019) as the majority of the values are derived from known methanol maser and ATLASGAL clump associations.

5.2. Association with radio continuum

In general, we do not expect to see a close relationship between methanol masers and radio emission from HII regions, as the latter is a more developed stage of HMSF where methanol maser emission begins to decline (e.g. Beuther et al. 2002). However, this may not necessarily be the case with regard to the properties and early evolution of the more compact HII regions, (i.e. hyper-compact (HC) and ultra-compact (UC) HII regions) as proposed, for instance, by Walsh et al. (1998); Yang et al. (2019a, 2021).

Fig. 19. Surface density plot of the offset of GLOSTAR radio continuum sources associated with GLOSTAR 6.7 GHz methanol masers.

These more compact HII regions are younger sites of HMSF and may still have maser emission in their surroundings as they evolve. This is supported by the observational results seen in Yang et al. (2021) from the largest sample of HC HII regions showing a maser detection rate of 100%, and the detection rate decreases as HII regions evolve from HC HII regions to UCHII regions. However, radio continuum emission at this stage is difficult to detect due to the compactness of the optically thick free-free radiation of HC HII, which results in low fluxes.

We attempted a search for associations of masers with the 5.8 GHz GLOSTAR D-configuration continuum (from $3^{\circ} < l < 60^{\circ}$). We find there to be 111 sources within $20''$, which is the size of the VLA D-array beam dropping to 64 when we use an angular distance threshold of $6''$. This threshold value corresponds to the 3σ level of the distribution shown in the source surface density plot in Fig. 19. This 12% association rate is smaller than that reported by Hu et al. (2016), with a better sensitivity of $\sim 45 \mu\text{Jy beam}^{-1}$ in the Galactic mid-plane for the radio continuum data; these authors found that $\sim 30\%$ of masers were associated with UCHII regions. This is not unexpected as the resolution of the D-configuration continuum catalogue is not as well suited to sampling UCHII and HC HII regions. The lack of association of 6.7 GHz methanol masers with radio continuum, however, indicates that these masers trace the earliest stages of high mass star formation.

We show (again) in Fig. 20 the flux distribution of the masers and their associations to continuum sources. By comparing the fraction of masers with an associated continuum source for each flux bin, there seems to be a trend in that the association with continuum sources increases with maser flux density. In Fig. 21, we show instead the flux distribution of the continuum sources to see if weaker radio sources (that are HII regions) are more correlated with methanol masers as it is possible to attribute weaker sources to younger stages of development. Despite the low association rate, we see that a Kolmogorov–Smirnov test of the distribution (bottom panel of Fig. 21) results in a p -value of $\ll 0.0013$, showing that there is a correlation with the continuum source flux for sources that have methanol maser associations. We see that radio sources with methanol masers are significantly brighter than the general population of radio sources.

Fig. 20. As Fig. 10 except for subsets of GLOSTAR maser detections that have GLOSTAR D-configuration continuum source detections.

Fig. 21. Flux density comparison between maser associated continuum sources and those without. *Top:* blue hatched histogram shows the flux distribution of the GLOSTAR D-configuration continuum sources (Medina et al. 2019, and in prep.). The orange histogram shows the distribution of the radio sources that are associated with GLOSTAR 6.7 GHz methanol masers and has been rescaled for better visibility (the axis is indicated on the right). *Bottom:* CDFs for the flux density of radio continuum sources that have 6.7 GHz methanol maser associations (blue) and those without (red). The result of the Kolmogorov-Smirnov test is reported above the figure and indicates that both distributions are distinct, with continuum sources associated with methanol masers typically being stronger than the overall distribution of continuum sources.

Fig. 22. Maser flux density against radio continuum flux density. Black crosses correspond to GLOSTAR D-configuration values for the radio continuum whereas blue crosses correspond to CORNISH B-configuration values. Blue circles show the sources that have counterparts in both continuum catalogues, but are plotted with the GLOSTAR flux density. Red circles denote sources that are new maser detections.

The true nature of the radio continuum sources, however, can be something other than HII regions, as they might be planetary nebulae, for instance, or they may even be extragalactic in origin. Following Medina et al. (2019), who determined that for the GLOSTAR D-configuration sensitivity there would be a source density of $0.0172 \text{ arcmin}^{-2}$, this suggests that there would be ~ 7600 extragalactic sources of this sort, which is close to 60% of the sources in the catalogue. As such, we need to take into account the likelihood of an extragalactic background source being inside our matching radius. This is given by $N_{\text{bg}} = (\text{source density}) \times (\text{search area})$. We used a search radius of 6 arcsec around the maser positions, which means that the estimated number of background sources is then $N_{\text{bg}} \ll 1$. This implies that line-of-sight associations between GLOSTAR 6.7 GHz masers and GLOSTAR 5.8 GHz radio-continuum sources have a low probability of being purely coincidental. We also used the CORNISH catalogue to supplement our comparison. They have classified their sources which helps us to determine the nature of the continuum sources we have associated with our methanol masers. We find that 34 masers have CORNISH counterparts, which are all labelled as UCHII regions. Of these associations, 15 do not have GLOSTAR D-configuration radio catalogue counterparts. These are likely involved in extended emission seen through the D-configuration. Conversely, 45 sources have GLOSTAR radio counterparts but no CORNISH counterparts. A future analysis of the sources' spectral index can provide further insight on the astrophysical nature of the remaining continuum sources (Medina et al., in prep.).

We show in Fig. 22 the maser flux density as a function of continuum flux density, using the CORNISH catalogue to supplement the GLOSTAR radio continuum catalogue, where we used the flux from GLOSTAR where available. The Spearman's rank coefficient is $r = -0.11$, with a p -value = 0.32, thereby showing no correlation between the properties. As discussed above, we know that there is a positional correlation between radio sources and methanol masers, however in Fig. 23, we do not see any relation between the flux of a maser and its proximity to the radio continuum source (Kolmogorov-Smirnov test results

Fig. 23. Methanol maser flux as a function of offset to the peak flux position of its associated radio continuum source.

of $r = -0.11$ and $p\text{-value} = 0.3$). If the methanol maser was intimately connected with the radio source, one would expect to see increasing maser strength with decreasing position offset. Given that the maser flux and continuum flux show no correlation and that there is no correlation with maser flux and position offset, this suggests that the mechanisms powering the two kinds of sources are unrelated as expected, despite there being a positional correlation.

5.3. Luminosity function

Given that the 6.7 GHz methanol maser is a tracer of HMSF, a luminosity function of these sources would allow us to compare the amount of HMSF in the Milky Way and other nearby Galaxies. Studies have shown that the luminosity function for these masers cannot be fit by a single power law but may be fit with a broken power law (Pestalozzi et al. 2007; Pandian et al. 2009; Green & McClure-Griffiths 2011). As discussed in Sect. 4.3, we have allocated distances to the maser sources using a Bayesian distance estimator as well as ATLASGAL clump velocities. However, if we were to use only the sources with an ATLASGAL association to determine the luminosity function, we would be biased towards sources with higher luminosities. This is evident in Fig. 24, which shows a clear fractional difference in the number of sources in the lower luminosity bins compared to the full sample to ATLASGAL CSC only sources. While a CDF of these two samples would show that they are not statistically distinct, which is to be expected, we do find that in examining the right panel of Fig. 24, we see that there is a statistical difference in maser properties between the sources with ATLASGAL counterparts and those without (Kolmogorov-Smirnov test result of $r = 0.74$ and $p\text{-value} \ll 0.0013$). As such, we chose to use the full sample. In Fig. 25, we plot the luminosity as a function of heliocentric distance. As expected, the new maser detections cover the lower luminosity ranges for a given distance. This also allows us to determine the completeness level. Given a minimum flux, we can calculate the minimum luminosity of a maser we can detect for a given heliocentric distance. This, in turn, can be turned around to give the maximum distance at which a maser of a given luminosity can be detected. Then, within the limits of the survey coverage, the fraction of the Milky Way disk covered at a given distance will give us the

completeness that has been normalised over the survey area. This is shown in the luminosity function in Fig. 26. We find that we are 100% complete at $6.9 \times 10^{-7} L_{\odot}$.

We also find that the median luminosity is $3 \times 10^{-6} L_{\odot}$ and this is in agreement with previous studies (e.g. Pandian et al. 2009) that report that the distribution peaks around $10^{-6} L_{\odot}$. Our sample size is about six times greater than that of Pandian et al. (2007, 2009) and, therefore, our median luminosity is statistically more robust. To characterise the luminosity function, we used only the luminosity bins for above which we are complete. We simultaneously fit two power laws and found indexes of 0.08 ± 0.05 for the lower luminosity range and -0.66 ± 0.05 for the higher luminosity range where the turnover has been determined to be $\sim 2 \times 10^{-5} L_{\odot}$. However, we see that while it is possible to fit a broken power law to the data, we do not sample well the lower luminosities, as our 100% completeness is around $6.9 \times 10^{-7} L_{\odot}$.

6. Summary and conclusions

In this work, we conduct the most sensitive, unbiased survey of Class II 6.7 GHz CH_3OH masers to date in the region covered by the GLOSTAR survey in the Galactic plane. A total of 554 masers were detected, with 84 of them being new detections. Over 50% of the new detections have fluxes of <0.5 Jy and it was possible to detect them thanks to the improved sensitivity of GLOSTAR as compared to other unbiased surveys. A summary of the main results of this work are as follows:

- In a comparing with the ATLASGAL Compact Source Catalogue (CSC), we find that 65% of the CH_3OH masers are associated with dense gas, with many of the newly detected masers remaining unassociated. However, a visual inspection reveals a much higher association rate of 97%, indicating that many of the new masers are associated with weak dust emission that is below the sensitivity required for inclusion in the ATLASGAL CSC.
- The newly detected masers are weaker both in terms of their maser emission and associated dust emission. This might indicate they are either more distant than the previously detected masers or could be associated with lower mass stars or less evolved stars. Given the lower range of maser luminosities and the fact that the L/M distribution of the new masers is consistent with the previous masers, this indicates that they are more likely to be associated with lower-mass stars.
- The high correlation between methanol masers and dust emission and the high bolometric luminosities are consistent with the picture of methanol masers being associated with the early stages of high-mass star formation. We derived an L/M threshold for the onset of the methanol maser emission of $\sim 1 L_{\odot} M_{\odot}^{-1}$, which is consistent with values determined by Ortiz-León et al. (2021) based on a study of the Cygnus X region with GLOSTAR data as well as a previous work on the MMB catalogue carried out by Billington et al. (2019).
- We find that 12% of the masers are coincident with radio continuum emission (i.e. $<12''$) but in comparing the radio and maser flux distribution, we find no correlation as a function of angular offset. This suggests that the mechanisms powering maser and continuum emission are unrelated.
- We used our sample of masers to construct a luminosity function using a broken power law. Our results agree with previous studies in that the distribution has a median luminosity $10^{-6} L_{\odot}$. We sampled the high-luminosity maser

Fig. 24. Comparison of the luminosities of sources with and without association with ATLASGAL sources. *Left:* shown is the distribution of the luminosities. The median value is $3.1 \times 10^{-6} L_{\odot}$ for the full sample and $4.7 \times 10^{-6} L_{\odot}$ and the subset of detections peaks that have ATLASGAL compact source catalogue (CSC) associations. *Middle:* CDF comparing the full sample of luminosities to the subset of sources that are associated with ATLASGAL where the two samples are not distinct. *Right:* CDF comparing the sample of luminosities without an ATLASGAL association to those with where they are seen to be statistically distinct.

Fig. 25. Maser integrated luminosity as a function of heliocentric distance marked as black crosses where red crosses highlight the new maser detections from this work. The blue curve denotes the 5σ luminosity threshold and the dotted blue line corresponds to the completeness level of 100%.

Fig. 26. Distribution of luminosities derived. The blue vertical line represents the median value of $3.1 \times 10^{-6} L_{\odot}$. The subset of new detections peaks at a lower luminosity as expected. The red curve corresponds to the completeness level with values on the right axis, and the dotted red line indicates the level of 100% completeness. The two green lines represent the broken power law fit with powers of 0.08 ± 0.05 for the lower luminosity range and -0.66 ± 0.05 for the upper luminosity range.

population with success, but we find we are limited with respect to the lower-luminosity bins.

This work is the first step in our study of 6.7 GHz CH_3OH masers using GLOSTAR data in the Galactic plane. Methanol absorption sources have also been detected and a systematic search is forthcoming. Further study of the properties of these masers would be best served with higher resolution data that we will present in future works.

Appendix A: The strongest new sources

Cutouts of the strongest new 6.7 GHz CH₃OH maser detections at their respective peak velocities. We visually inspected these sources that should have been detected by the MMB given their high fluxes. While some sources were probably missed previously due to its proximity to a stronger maser source, it is likely maser variability that plays a role in their previous non-detection.

Appendix B: Association of masers with weaker ATLASGAL emission

We visually inspected all maser positions that were not automatically matched with an ATLASGAL CSC counterpart for dust emission and find that most of them are still associated with dust.

Appendix C: The spectra of CH₃OH masers

Here, we present the spectra for each maser source.

Fig. A.1: GLOSTAR 6.7 GHz emission maps at the velocity of the maser emission peak of the ten strongest new masers, denoted by the magenta ‘X’. Red triangles denote the position of known MMB masers. The flux levels were limited to 75% of the maser peak to better illustrate low intensity features. The white “+” signs show the positions of known compact ATLASGAL sources and the white contours are from the ATLASGAL 870 μ m dust emission map with contour levels at -3, 3, 5, 7, and 10 σ noise levels.

Fig. A.2: Fig. A.1. continued.

Fig. B.1: ATLASGAL 870 μm dust continuum cutouts centred on the position of a given maser, shown as a magenta 'X'. The white '+' is the position of an ATLASGAL compact source from the compact source catalogue (CSC). The white contours are the ATLASGAL 1, 2, 3, and 4 σ levels, where the red contour is the 5 σ level. The left panel shows an example where it is clear that the methanol maser is associated with dust emission above 5 σ , but farther than the 12'' used for the association. The right panel shows an example of a weak compact source that shows a maser association, but was not considered for the ATLASGAL CSC. However, the association with the maser makes a strong argument for the veracity of the weak compact source.

Fig. C.1: Spectra of 6.7 GHz methanol masers detected with GLOSTAR extracted at the peak pixel. The red dashed line indicates the ATLASGAL clump velocity (Urquhart et al. 2018, 2022) in case of an associated 870 μ m compact source catalog (CSC) source.
