Abstract. Polymorphism in ML is implicit: type variables are silently introduced and eliminated. The lack of an explicit declaration of type variables restricts the expressiveness of parameterised modules (functors). Certain polymorphic functions cannot be expressed as functors, because implicit type parameters of polymorphic functions are in one respect more powerful than formal type parameters of functors.

The title suggests that this lack of expressiveness is due to a restricted ability to abstract — polymorphism is restricted. Type variables can only be abstracted from value declarations, but not from other forms of declarations, especially not from structure declarations.

The paper shows in the case of Standard ML how (syntax and) semantics can be modified to fill this language gap. This is not so much a question of programming language design as a contribution for better understanding the relationship between polymorphic functions, polymorphic types, and functors.

1 Introduction

Hindley-Milner polymorphism [6, 14] is the basis of the type systems of most modern functional programming languages. The computational, dynamic aspects of polymorphism are well-understood and the reader is assumed to be familiar with them. Less well-understood are the static aspects of polymorphism.

Polymorphism (for values) is introduced whenever type variables are abstracted in a value declaration. However, wide-spread functional languages like Standard ML [17] (SML for short) and Miranda² [8] have no corresponding introduction of polymorphism for arbitrary declarations, in particular polymorphism for modules is entirely missing. In practise, this is not a problem for languages which do not support parameterised modules, e.g. Haskell [9]. In the following we shall stick to SML, mainly because its formal definition [16] enables us to discuss the semantic issues involved; apart from that, this choice is not essential: the only essential ingredients for our approach are ML-style polymorphism and the presence of parameterised modules.

The lack of polymorphism for structures (modules in SML) can be illustrated by comparing the expressive powers of functors (parameterised modules in SML) and polymorphic functions.

 $^{^{\}star}$ The research reported here was supported by SERC grant GR/J 07303.

² Miranda is a trademark of Research Software Ltd.

The function foldleft is polymorphic; the type of the parameter (f,n) is $(\alpha * \beta \to \beta) * \beta$ for arbitrary types α and β . One can think of α and β as implicit type parameters of foldleft. We can try to make this explicit by turning foldleft into a functor:

The polymorphic function foldleft and the functor FOLDLEFT seem to have equal expressive power in the following sense: whenever we can write a value declaration that instantiates foldleft with its first argument, like

```
val foldinstance = foldleft exp;
```

then there is an equivalent instantiation of the functor FOLDLEFT:

```
local structure Aux =
   FOLDLEFT(type A = ...; type B = ...
        val (f,n) = exp)
in   val foldinstance = Aux.foldleft
end;
```

The only problems here are the ellipses which have to be replaced by appropriate type expressions. Since these types can be inferred from exp, this does not seem to be a real problem. However, there is one, and we can observe it when considering the standard example of instantiation of foldleft, list reversal:

```
val reverse = foldleft (op ::,nil);
```

This is a *polymorphic* instantiation of foldleft: the defined function reverse is itself polymorphic. Hence, one might expect the appropriate type declarations in the corresponding instantiation of FOLDLEFT to be: type A = 'a and type B = 'a list. But it is unclear where the type variable 'a comes from, and indeed type declarations of this form are illegal in SML (and Miranda) — type variables on the right-hand side of a type declaration have to be introduced on the left-hand side. The reason for this restriction is partly a concern about soundness, and partly lack of imagination (or desire for simplicity) on the side of the language designers.

I will show how this restriction can (safely) be eliminated, i.e. in what way the syntax and semantics of SML can be modified to support polymorphism for structures and functors.

2 Polymorphism vs. Functors

Parameterised modules in SML are called *functors*. A functor maps structures that match its interface (a *signature*) to structures. SML functors are similar to parameterised "scripts" in Miranda [8] and parameterised "modules" in ET [3].

SML functors generalise polymorphic functions in the following sense. Parameters of polymorphic functions are types (implicit) and values (explicit). Functor parameters can be (polymorphic) values, (parameterised) types, and structures. Therefore, a functor can be supplied with the arguments of a polymorphic function via its input signature. The example of foldleft and FOLDLEFT (motivated by section 9.3 in [18]) illustrates how a functor can simulate a polymorphic function, but also in which way this simulation is restricted. Apart from that, functors are more powerful than polymorphic functions, because the value parameters can themselves be polymorphic and because the type parameters can be parametric. Here is an example (adapted from [19]) that shows the extra power of functors.

```
signature MONAD =
    sig
        type 'a M
        val unitM: 'a -> 'a M
        val bindM: 'a M -> ('a -> 'b M) -> 'b M
    end;
functor Monad(include MONAD) =
    struct
        fun mapM f m = bindM m (unitM o f)
        fun joinM z = bindM z (fn x => x)
    end;
```

The functor Monad and the signature MONAD both use the formal parameterised type associated with M with different arguments, in particular joinM has type ('a M) M -> 'a M. Analogously, the polymorphic function bindM is used with different type instances in the body of the functor. This cannot be expressed with polymorphic functions; $\lambda \omega$ is the weakest type system in Barendregt's λ -cube [1] that can express the Monad functor.

Our goal is to make functors properly more powerful than polymorphic functions — not so much because this lacking power is badly missed in programming practice, but in pursuit of a better understanding of the two concepts. We shall first look at ways to circumvent the restriction of polymorphic functor instantiations in the existing language.

It is still possible to define a uniform list reversal as an instance of FOLDLEFT, but not as a polymorphic function — we can define it as a functor:

Syntactic restrictions for functor instantiation make the usage of the functor REVERSE slightly awkward — it is not possible to instantiate a functor within an expression, for example as in REVERSE(type T=int).foldleft[1,2,3]; the functor instantiation has first to be assigned to a structure name via a structure declaration. Again this means that the polymorphic use of REVERSE within the definition of a polymorphic function is not possible, unless the polymorphic function is turned into a functor. In Miranda, the analogous situation is even worse, because each parameterised module is a file.

It should be emphasised that these restrictions on functor usage are not merely syntactical accidents; they are deliberate design decisions in the concerned languages to keep all type-checking at compile-time. See [4] for a discussion on this *phase distinction*.

The problem of polymorphic instantiations of a functor has been noticed before, for instance by Hinze in [7]. The solution suggested there is to make formal type parameters of the functor parametric. In our FOLDLEFT example, this concerns its type parameters A and B; with the so-modified functor we can define a polymorphic reverse by functor instantiation³.

The new functor FOLDLEFT_1 is not restricted to non-monomorphic applications, because type declarations like type 'a A = int that erase a type argument are legal in SML. Indeed, FOLDLEFT can be expressed as an instance of FOLDLEFT_1. But this approach has two snags. The type parameters for A and B have nothing to do with the functor itself: neither its interface nor its body apply A or B to anything different from a type variable. From a methodological point of view, the functor interface is therefore a bad place for introducing these type parameters. More importantly, we have not really solved yet the problem of how to get a polymorphic function, which is an instance of foldleft, by instantiating the corresponding functor — only the special case where polymorphism is restricted to at most one type parameter. For example, we cannot define the (fully) polymorphic function map by instantiating FOLDLEFT_1, because map is parametric in two type variables. Of course, we can again abstract a further variable and

³ Some SML implementations struggle with this example, but it is perfectly legal.

define another functor FOLDLEFT_2, but each abstraction step makes the syntax of the functor (and its monomorphic instantiations) increasingly messy without solving the general problem.

We can observe the limitations of functor polymorphism more clearly in the Monad example. One of the classic examples for monads are continuation monads (also adapted from [19]):

```
structure Contin: MONAD =
    struct
    type 'a M = ('a -> Answer) -> Answer
    fun unitM a = fn c => c a
    fun bindM m k = fn c => m (fn a => k a c)
    end;
structure ContMon = Monad(open Contin);
```

Wadler suggests various choices for type Answer. We can express this in SML by turning the above piece of code into a functor with parameter Answer. However, this would enforce a new instance of Monad for every choice for Answer which is a bit of a waste. Instead, it would be more natural to replace Answer by a free type variable 'b, giving us a polymorphic continuation monad.

3 Polymorphism in SML

The example of foldleft shows how polymorphism is usually treated in SML and many related languages. The polymorphism of foldleft has been silently introduced; we can see this more clearly by mixing the explicit polymorphism of the type system $\lambda 2$ with ML code:

```
val rec foldleft = \lambda \alpha : *. \lambda \beta : *.

fn (f:\alpha \times \beta \to \beta,n:\beta) => fn ls:\alpha list => case ls of nil \alpha => n

| (op ::) \alpha (x,xs) => foldleft \alpha \beta (f,f(x,n)) xs
```

The * is the universe of types, i.e. $\lambda \alpha$: * denotes type variable abstraction in $\lambda 2$, see [1]. Instantiation of polymorphic values with types (application $t\tau$ of terms t to types τ in $\lambda 2$) is implicit in ML; similarly the introduction of types with variables like α for value expressions. On the level of types, application and abstraction of types are always explicit, for example in the declaration of type list:

```
datatype 'a list = nil | :: of 'a * 'a list
```

Here we have an explicit type variable 'a, its explicit abstraction on the left-hand side and an explicit type application, 'a list on the right-hand side.

This syntactic difference in polymorphism has a semantic equivalent — SML uses two different notions of type variable abstraction for values and types, called type schemes and type functions. The type function $\Lambda \alpha.\alpha t$ is the semantic value

of list (t is a $type\ name$, a kind of personal identification number for a type), the type scheme $\forall \alpha. \alpha t$ is the static semantic value of nil; type names have an arity and (constructed) types are formed by applying an n-ary type name to n types, type name application being written postfix. The difference between type functions and type schemes is that instantiation of bound type variables is always explicit for type functions and always implicit for type schemes. The semantic reason for distinguishing these two forms of abstraction is certain equivalences that apply to type schemes: for example, the type schemes $\forall \alpha \forall \beta. \tau$ and $\forall \beta \forall \alpha. \tau$ are equal, but the corresponding type functions $\Lambda \alpha \Lambda \beta. \tau$ and $\Lambda \beta \Lambda \alpha. \tau$ are different, provided α or β occurs in τ .

There is another important difference between polymorphism for values and polymorphism for types in SML: the effect of nested declarations. Instead of defining foldleft by direct recursion, we can exploit the fact that f is fixed throughout the recursion (cf. FOLDLEFT above):

The local function loop is monomorphic, it does not abstract type variables. We can see this by annotating the ML code with type abstractions and applications (exercise for the reader). However, the declaration of loop still contains (implicitly) a free type variable α for the instantiation of the list constructors nil and ::. This type variable is introduced in the context of the declaration of loop.

Concerning type declarations, the rôle of nested declarations is different. Although a type declaration can occur in a context which contains free type variables (in SML; not in Miranda), all type variables occurring on its right-hand side *must* be declared on its left-hand side, they cannot come from the context. The language definition of SML imposes this restriction.

We want to lift this syntactic restriction, because it prevents us from writing the polymorphic functor instantiations. This raises the question how free type variables are introduced and eliminated, and in particular what the semantic equivalent of the elimination operation is.

4 Type Variable Declarations

Before we consider the introduction and elimination of type variables for arbitrary declarations, let us look at the semantic rule⁴ that defines the corresponding operation for value declarations, i.e. that introduces type schemes for value variables — rule 17 in the definition of the static semantics of SML [16]:

⁴ The rule presented here is a simplified version — I have removed the parts that deal with imperative type variables, as they have no particular significance in this context.

$$\frac{C + U \vdash valbind \Rightarrow VE \qquad VE' = Clos_CVE}{C \vdash \mathtt{val}_U \ valbind \Rightarrow VE' \ \text{in} \ Env}$$

The non-terminal valbind stands for a value declaration. Sentences of the semantics of SML of the form $C \vdash phrase \Rightarrow VE$ can be read as: in the context C the syntactical phrase phrase gives rise to (elaborates to is the technical term) a variable environment VE. Variable environments bind identifiers to their type schemes; they also occur as components of general environments ($E \in Env$) that can contain other bindings as well. "VE' in Env" is a general environment containing the variable environment VE' but no other bindings.

C+U is a context in which type variables from U are declared to be free and $Clos_CVE$ is a variable environment obtained from VE by abstracting all type variables not free in C; this abstraction introduces type schemes, pointwise for each variable bound in VE. It may be a bit surprising that the result of a type variable abstraction from a variable environment is not a mapping from types to variable environments, but another variable environment. The justification goes as follows: a (static) variable environment can be seen as a tuple of types (or rather type schemes), indexed by the bound identifiers. If we extend the type system $\lambda 2$ with binary products, the following types are "isomorphic":

$$\Pi \alpha : *. (T(\alpha) \times U(\alpha)) \cong (\Pi \alpha : *. T(\alpha)) \times (\Pi \beta : *. U(\beta))$$

The abstraction on the left-hand side abstracts a type variable from a tuple, the right-hand side is a tuple (type) of abstractions. For instance, the mapping from left to right can be given as the expression $\lambda x : P.(\lambda \alpha : *. \pi_1(x\alpha), \lambda \beta : *. \pi_2(x\beta))$ in $\lambda 2$, where P is the type on the left-hand side of \cong .

I write "isomorphic" in quotes, because they are only isomorphic in a weak sense as indicated by Di Cosmo in [2]: we have to impose a few equivalences to make the composition of both mappings equal to the identity. These equivalences are $=_{\beta\eta}$, surjective pairing, and the equation (fx,gx)=(f,g)x. This weak isomorphism is the justification (in SML) for performing the abstraction pointwise, i.e. for picking the type on the right.

Coming back to the mentioned semantic rule in SML, it contains another slightly mysterious bit. The subscript U in val_U valbind is the set of type variables scoped at this value declaration. In other words: the rule incorporates introduction and elimination of free type variables. For value polymorphism, the scoping of type variables is a minor issue as it deals only with type variables that occur explicitly in the text while type scheme polymorphism is mainly tacit and operates on implicit type variables. Explicit type variables are not introduced by an explicit declaration, but rather attached to a value declaration by a general principle. Allowing free type variables to occur in other forms of declarations raises the need for an explicit form of type variable declaration. For the purposes of this paper, I suggest typevars tyvarseq as an additional form of declaration. The corresponding rule in the static semantics is quite simple:

4.1 Abstraction: General Idea

Type variables are not bound to anything⁵, so an environment simply contains a sequence of non-empty sequences of type variables, listing the free type variables in that environment. We shall see later why the semantic value of a type variable declaration is a *sequence of sequences* rather than a *set* of type variables. Semantically more interesting than introduction is elimination of free type variables. It seems natural to let type variable declarations follow the usual scoping rules for declarations and eliminate them at the end of their scope, for example by modifying the rule for local declarations accordingly:

$$\frac{C \vdash dec_1 \Rightarrow E_1 \qquad C \oplus E_1 \vdash dec_2 \Rightarrow E_2}{C \vdash \mathsf{local}\ dec_1\ \mathsf{in}\ dec_2\ \mathsf{end} \Rightarrow abstract_C(U\ of\ E_1)(E_2)}$$

A local declaration local dec_1 in dec_2 end declares whatever dec_2 declares; the declarations in dec_1 are auxiliary for dec_2 and their scope ends at the keyword end. Thus, if dec_1 contains type variable declarations their scope also ends at the end of the local declaration.

The difference from SML's rule for local declaration is the application of the abstraction operator to E_2 in the conclusion, rather than taking E_2 itself as the result. It would follow more closely the style of the SML definition if the abstraction were expressed as $Clos_C E_2$, but there is a problem: the operation $Clos_C$ abstracts all type variables which are free in its argument and not free in C, but the order of abstraction is significant for type functions and hence for our generalised abstraction as well. I postpone the definition of abstract, until it is clearer which properties it should have. Consider an example that uses the feature of type variable declarations:

Notice that the type variable 'a in the declaration of list does *not* come from the left-hand side but from the context of the declaration. Within the local declaration, list is a monomorphic type and foldleft is only polymorphic in one type variable, its result type.

For merely pragmatic reasons, it is desirable to abstract type variables pointwise from the components of an environment. The components which matter in this respect are (i) type schemes, the semantic values of value variables, (ii) type functions, the semantic values of type constructors, and (iii) type names, the personal identification numbers of newly introduced constructed types.

⁵ One can think of a type variable as an ordinary variable bound to *, as in $\lambda 2$.

4.2 Abstraction: Gory Details

We would certainly like the abstraction operator to behave on type schemes just as $Clos_C$ does, i.e. to increase the set of abstracted type variables of a type scheme: type abstraction introduces polymorphism. This principle already allows us to formulate reverse as an instance of FOLDLEFT:

The only item that is subject to type variable abstraction in this example is the type of reverse, because its declaration is the only non-local one. Within the local declaration, reverse has the monomorphic type 'a list \rightarrow 'a list, but 'a can be abstracted at the end of the local declaration, introducing a polymorphic reverse.

Abstracting a type variable from a type name increases the arity of that type name: the arity of list inside the local declaration is 0, but it is 1 outside, as we want be able to instantiate 'a with various types and as we have to distinguish these different instantiations semantically to preserve the soundness of the type system. We only need to abstract type variables on which a type name depends; in the example, list depends on 'a, because 'a occurs freely in its constructor environment. For simplicity, we can assume that all (new) type names depend on all abstracted type variables.

The change of arity of a type name slightly complicates abstraction in the variable environment case, as further components of the environment may contain that type name and are thus affected by such a change: an environment is like a *dependent* n-tuple and we need weak isomorphisms operating on dependent tuples (see [13] for an introduction to Σ -types), in the binary case as follows:

```
\Pi\alpha: *. \Sigma x: T(\alpha). U(\alpha, x) \cong \Sigma x: (\Pi\alpha: *. T(\alpha)). \Pi\beta: *. U(\beta, x\beta)
```

Notice that x on the left-hand and right-hand side of the \cong has different arities; this corresponds to the different arities of a type name. Fortunately, this weak isomorphism exists and is similarly straightforward as in the non-dependent case.

One case remains: type variable abstraction for type functions. We could stick to the principle that type abstraction always introduces *implicit* polymorphism, so that a type function may have explicit *and* implicit parameters. In the example it would mean that list has an *implicit* parameter outside the local declaration and that it would be the task of type inference to compute it, similarly as it computes the implicit type parameter of nil. This is surely possible but

seems rather unusual and involves a number of language design problems, e.g. its interaction with the module system or whether it would be possible to restrict implicit polymorphism in type expressions. I shall not pursue this approach here.

The alternative is to turn abstracted type variables into *explicit* parameters of a type function. Since these additional parameters are explicit, there is a corresponding effect on the syntactical level: the arities of *type constructors* change as well. In the example, the type constructor list has arity 1 outside the local declaration: it requires an argument when used in type expressions.

To be able to change the arity of local type names, it would be useful to explicitly keep track of local type names as an additional component of environments. Implementations do that anyway, and some arguments why the SML definition should also be explicit about it can be found in section 9.2 of [10].

SML already provides a mechanism to replace type names: these are the so-called realisations which are used for structure/signature matching. Basically, a realisation is a finite map from k-ary type names to k-ary type functions; it can be applied to various semantic objects by replacing the type names throughout the object. Realisation application can be seen as second-order substitution.

For the abstraction operation, such functions are more complicated, i.e. we need more structure for realisations, type functions etc.

- Analogously to type declarations, type functions can now contain free type variables.
- The arity of a type name (or a type function) in SML is a natural number n; it is convenient to generalise this to a sequence of natural numbers n^* , which notationally supports curried application of type constructors.
- A realisation in SML maps a k-ary type name to a k-ary type function; here, if we abstract a sequence α^* of non-empty sequences of type variables from an environment, the corresponding abstraction realisation maps k^* -ary type names to $n^* \cdot k^*$ -ary type functions, where \cdot is list concatenation and n^* = map length α^* .

Let C be a fixed context and α^* be a fixed sequence of non-empty sequences of type variables and $n^* = \text{map length } \alpha^*$. An abstraction realisation φ is an injective map from k^* -ary type names (not in C) to $n^* \cdot k^*$ -ary type names (also not in C). We need injectivity and disjointness from the type names in C in the result to preserve the soundness of the type system⁶. Because the arity of type names is not preserved, we have to redefine the application of abstraction realisations to constructed types:

$$t \in Dom \varphi \Rightarrow \varphi(\tau^* \ t) = (\alpha^* \cdot \varphi(\tau^*)) \ \varphi(t)$$

$$t \notin Dom \varphi \Rightarrow \varphi(\tau^* \ t) = \varphi(\tau^*) \ t$$

where τ^* is a sequence of non-empty sequences of types and t is a type name. Furthermore the arity of type function changes, i.e. $\varphi(\Lambda\beta^*.\tau) = \Lambda\alpha^*\beta^*.\varphi(\tau)$.

 $^{^6}$ A technical remark: unfortunately, the consistency condition for semantic objects is too weak for this purpose.

Now we can define $abstract_C(\alpha^*)(E)$ as $Clos_C(\varphi E)$ where φ is an arbitrary abstraction realisation w.r.t. context C and type variables α^* , which is defined on all type names in E that are not in C. The closure operator $Clos_C$ introduces type schemes in variable (and constructor) environments.

From the language design point of view, the abstraction operator has another merit. It allows to separate type abstractions from datatype declarations. There are some reasons to enforce this separation as the only form for recursive type declarations. The static semantic rules for value declarations use the same structure, i.e. type variable abstraction is imposed after the recursion has been solved. Because of this, it is not possible to define structurally inductive functions (which pass SML's type-check) for certain recursive types.

Strengthening the static semantic rules for value declarations such that structurally inductive functions for all recursive datatypes are typable makes typability [1] undecidable, because this is equivalent to solving arbitrary semi-unification problems [11]. Although "undecidable" surprisingly does not imply "impractical" in this case (see [5]), a type-checker that is necessarily non-terminating for some inputs may make some people feel uncomfortable. Having abstraction and datatype declaration as two separate concepts allows to impose the same restrictions on recursive types as on recursive functions, such that any recursive type has its corresponding recursive functions and vice versa.

5 Imperative Features

Naive polymorphism is unsound in connection with certain imperative features, for example it is unsound to have updatable polymorphic variables (references). For this reason, SML has a second form of type variables, imperative type variables. Abstraction from imperative type variables is restricted to so-called non-expansive objects; non-expansiveness is a sufficient condition for preventing polymorphic references and exceptions.

Standard ML implements this restriction by modifying its abstraction operator Clos and making $Clos_CVE$ dependent on whether VE was derived from an expansive (value) declaration or not. A similar modification would be necessary for our generalised abstraction operator. For example, we could regard a sequence of declarations (a structure) as expansive if any of its elementary declarations is expansive; the expansive elementary declarations consist of exception declarations and expansive value declarations. An attempt to abstract imperative type variables from an environment which was derived from an expansive structure could then be regarded as an error.

But this is not the only difficulty. Since we can now also abstract type variables from type constructors, we have additional problems: the abstraction may put *applicative* type variables (unrestricted polymorphism) into places where they should not be, example:

```
functor EXCEPT(type t) =
    struct exception A of t end;
structure S = let typevars 'a in EXCEPT(type t = 'a) end;
```

The component type of an exception is not allowed to contain applicative type variables (for soundness reasons; see [15], page 42), but in the above example abstraction and module instantiation unfortunately outwit this restriction.

The straightforward solution is to supply type names with an additional "imperative" attribute (similar to the equality attribute) and to require realisations to assign only imperative types to imperative type names. The example would be ruled out, as t is imperative and 'a is not. Even with imperative type variables there are problems here, because functor bodies can be expansive, as the example shows. One possible way of solving this problem is to require that formal imperative type names are mapped by a realisation to closed imperative types; in other words: to essentially restrict generalised type abstraction to the applicative case.

The presence of non-imperative type names has a number of other effects on the language.

- A type τ^* t is imperative if t is an imperative type name and all types in τ^* are imperative. This implies a restriction on specialisation of imperative polymorphism and the types of exception constructors.
- We have to compute an imperative attribute for newly introduced datatypes. This is completely analogous to the equality attribute, i.e. a new datatype is imperative if (roughly) all its constructors have imperative types as argument types.
- We need a feature to specify the imperative attribute of a formal type parameter of a functor, analogous to eqtype for the specification of the equality attribute. To keep the extension upwards-compatible with the existing language, we can take a type specification type ty to specify that ty is imperative and add a feature for the specification of (possibly) non-imperative types.

A nice side-effect of this approach is that the attributes for equality and imperativeness are treated completely analogous, i.e. they are attributes of type names and type variables. This fits very well with a Haskell-like understanding of these attributes as type classes.

Instead of this rather sophisticated approach to imperative features, one could instead employ the method suggested by Leroy in Chapter 6 of his thesis [12]. It can be roughly described by the slogan: "type variable abstraction introduces closures", i.e. (even implicit) type application forces re-evaluation. This method eliminates all soundness problems with imperative features, including the ones mentioned in this section.

6 Related Module Systems

In the following, we briefly discuss the (potential) rôle of type variable abstraction in the module systems of ET [3] and Miranda [8, 7].

The (functional logic) programming language ET is the only programming language with a notion of polymorphic abstraction for types I am aware of. Because ET's module system is flat (no substructures) and because type declarations are only permitted at top level, ET has only one place for free type variables — instantiation of functors. Type variables can be locally free for a functor instantiation. In ML syntax, ET's functor instantiations all have the following shape:

The semantic operations that support such a notation in ET differ slightly from the method described above for SML. Type declarations in the functor argument are required to be non-parametric, i.e. the corresponding type functions are of arity 0. For the functor body, these types are treated like free type variables and are abstracted from the exported objects. A functor instance (with or without free type variables) instantiates these variables with actual types and restores the old arity of all type constructors, before all free type variables of the functor instance are abstracted.

The difference to the method described for SML is in sharing of types. The first abstraction does not depend on the module instance and is performed only once — an ET functor contains free type names, in contrast to SML where each functor instance makes a fresh copy of these type names. Thus, types obtained from different functor instances in ET are compatible and an ET functor application never generates new datatypes. In other words: ET functors are extensional — applied to the same arguments they deliver the same results.

6.2 Miranda

Miranda's module system has a similar structure to ET: modules are flat and types only exist on top level, but it does not support type variable abstraction from functor instances. Concerning type compatibility of functor instances, Miranda follows SML. Since the specification of parameterised types in functor interfaces is possible, ET's approach is not feasible anyway, because this would require third order type constructors and second order type variables, making type inference undecidable.

Miranda supports recursive functor instantiation, i.e. the exported objects of a functor can be used to provide it with its input parameters. It is possible to create recursive types by recursive functor instantiation. For the abstraction of type variables, here we have again the problem whether abstraction and recursion take place simultaneously, or whether abstraction is imposed after the recursion. An example (in ML-style syntax) should make it clear:

```
functor COPY (type t) =
    struct
        type u = t
    end;
structure rec C =
    let typevars 'a
    in COPY(datatype t = nil | cons of 'a * 'a C.u)
    end:
```

The functor COPY exports the non-parameterised type u, which abstraction makes u parametric *before* it is stored in C, i.e. C.u is parametric and has to be provided with an argument even in recursive occurrences. One can also express abstraction *after* recursion by moving the declaration of 'a outside:

In this slight modification of the last example, C.u is non-parametric within the recursion, but becomes a parametric type at the end of the local.

7 Conclusion

Polymorphism in languages like Standard ML or Miranda is restricted because it allows to abstract type variables from declarations of values but not from declarations of types or structures. In this sense, polymorphism is not first-class. This restriction can be felt in the presence of parameterised modules, which in a strange way happen to be less expressive than polymorphic functions.

The syntactic cure is simple and — important from a language design point of view — easy to understand: introduce a new form of declaration, the explicit declaration of type variables. Such type variables are abstracted at the end of their scope. The semantic cure is a little bit more subtle, because type variable abstraction has to be defined for all possible environment components.

Such pointwise type variable abstraction from environment components is justified, for one can consider the global abstraction of types from a tuple to be isomorphic to the tuple with pointwise abstracted types. This isomorphism has already been exploited in the semantics of Standard ML and Miranda, but it becomes slightly more complicated in this setting as (general) environments have to be regarded as *dependent* tuples.

Acknowledgements

I would like to thank Bernd Gersdorf, Claudio Russo, Don Sannella and Andrzej Tarlecki and the ESOP referees for valuable discussions on this subject and feedback on an earlier version of this paper.
