45 **ABSTRACT**

46 Purpose. To assess the reliability and construct validity of a selfpaced, submaximal run test (SRT_{RPE}) for monitoring aerobic 47 48 fitness. The SRT_{RPE} monitors running velocity (v), heart rate 49 (HR_{ex}) and blood lactate concentration (B[La]) during three, 3-

50 min stages prescribed by Ratings of Perceived Exertion (RPE)

51 10, 13 and 17.

52 *Methods*. Forty, (14 female), trained endurance runners 53 completed a treadmill graded exercise test (GXT) for 54 determination of maximal oxygen consumption (VO_{2max}), velocity at $\dot{V}O_{2max}$ ($\dot{V}\dot{V}O_{2max}$) and velocity at 2 mmol·L⁻¹ (vLT1) 55 and 4 mmol·L⁻¹ (vLT2) B[La]. Within 7-days, participants 56 57 completed the SRT_{RPE}. Convergent validity between the SRT_{RPE} and GXT parameters was assessed through linear regression. 58 59 Eleven participants completed a further two trials of the SRT_{RPE}

60 within a 72-hour period, to quantify test-retest reliability.

61 **Results.** There were large correlations between v at all stages of the SRT_{RPE} and $\dot{V}O_{2max}$ (r range = 0.57–0.63), $v\dot{V}O_{2max}$ (0.50– 62 0.66) and vLT2 (0.51-0.62), with vRPE 17 displaying the 63 64 strongest associations (r > 0.60). Intraclass correlation 65 coefficients (ICC_{3,1}) were moderate to high for parameters, v 66 (range = 0.76-0.84), HR_{ex} (0.72-0.92) and %HR_{max} (0.64-0.89) at all stages of the SRT_{RPE}. The corresponding coefficients of 67 variation were 2.5–5.6%. All parameters monitored at intensity 68 69 RPE 17 displayed the greatest reliability.

70 *Conclusion.* The SRT_{RPE} was shown to be a valid and reliable test for monitoring parameters associated with aerobic fitness, 71 72 displaying the potential of this non-invasive, time efficient test 73 to monitor responses to endurance training.

INTRODUCTION

The frequent and reliable monitoring of an individuals' responses to endurance training is an important component within the management of appropriate training stress and recovery¹.

Endurance performance is determined by the level of aerobic metabolism that can be maintained during a race (performance $\dot{V}O_2$)². Performance $\dot{V}O_2$ is dictated by the upper limit for ATP production via oxidative phosphorylation (VO_{2max}) and fraction of VO_{2max} that can be sustained (influenced by the lactate threshold and running economy)². Although these parameters (VO_{2max}, lactate threshold and running economy) are often analysed using a treadmill-based graded exercise test (GXT) to assess the construct of aerobic fitness in runners²⁻⁴, their analysis for the purpose of monitoring acute within-subject responses to training has limitations. Specifically, in homogenous cohorts of runners, $\dot{V}O_{2max}$ has shown a low association with competitive performance 5,6 and low sensitivity to within-subject variation in performance following training4. Comparatively, velocity at VO_{2max} (vVO_{2max}) and velocity at 4 mmol·L⁻¹ blood lactate concentration (vLT2), has shown greater associations to withinindividual changes in endurance running performance⁴. However, the traditional analysis of vVO_{2max} and vLT2 by the GXT requires expensive equipment, invasive procedures (blood sampling) and tester expertise, making this protocol inappropriate for regular monitoring and largely inaccessible.

Outside of a laboratory setting, aerobic fitness can be indirectly assessed through track-based multistage maximal exercise tests⁷ or distance⁴ and time⁶ fixed time-trials. The submaximal components of aerobic fitness (upper limit of sustainable velocity) can be evaluated through the assessment of critical velocity from three, maximal effort time-trials over variable distances (1200m–3600m)⁸. However, although more accessible, these protocols require athletes to perform to exhaustion, making them inadequate for the regular monitoring of athletes' responses alongside training.

 The Lamberts Submaximal Cycle Test (LSCT) is a practical exercise test which can be integrated into training as a warm-up. This test monitors performance output (power output/running velocity) and Ratings of Perceived Exertion (RPE) in response to three, short incremental exercise bouts (3–6-mins), fixed by a relative internal load of 60%, 80% and 90% heart rate maximum (HR_{max})^{9,10}. In an adaptation for runners, the velocity (v) monitored in an outdoor setting at 60%, 80% and 90% HR_{max} has been shown to be positively associated with aerobic fitness parameters; $\dot{V}O_{2max}$ (r range = 0.58–0.75)¹⁰ and vLT2 (0.79–0.89), suggesting that submaximal performance within this field-

based test offers good construct validity in relation to aerobic fitness.

127

128 However, this protocol may be limited by monitoring individual's responses to fixed intensities prescribed by a 129 %HR_{max}. Firstly, this does not completely relinquish the 130 131 requirement for athletes to complete a test to exhaustion. Furthermore, standardising the intensity of each stage by 132 133 %HR_{max}, likely leads to large inter-individual differences in 134 metabolic, perceptual and performance responses (e.g. blood 135 lactate responses and RPE), due to the inter-individual variations 136 in the location of metabolic thresholds (lactate thresholds) 137 between the stage intensities of 60%–90% HR_{max}¹¹.

138

139 In response to these limitations, we aim to explore the utility of a self-paced submaximal run test (SRT_{RPE}) which monitors v, 140 141 heart rate (HR_{ex}) and blood lactate concentration (B[La]) responses to three, 3-min stages prescribed by RPE 10, 13 and 142 17¹². The prescription of intensity by RPE may provide a 143 144 practical alternative which will not require prior completion of a GXT to exhaustion and more validly represents the pacing 145 146 demands of competitive endurance running. Importantly, the 147 vLT2 has consistently been appraised by RPE values 12-14, regardless of sex or competitive level and despite large inter-148 149 individual differences in the %VO_{2max} or %HR_{max} at this threshold^{11,13}. Therefore, the particular intensities prescribed by 150 151 the SRT_{RPE} (RPE 10, 13 and 17) may provide better insight into the training effect on performance corresponding to below, 152 153 approximately at, or above vLT2. Lastly, the use of 3-min stages is suggested as adequate to allow steady state v^{14,15} 154 reached, whilst minimising the time required for testing 155 compared to similar submaximal protocols (i.e. ~6-mins less 156 157 versus LSCT).

161 162

163

164

165

166

167

168

With these developments in mind¹⁶, the potential effectiveness of the SRT_{RPE} is dependent on its relative levels of validity and reliability^{17,18}. As the SRT_{RPE} aims to monitor a construct of fitness (aerobic fitness), validity can be determined by the magnitude of correlation between SRT_{RPE} parameters and other accepted determinant of this fitness construct (VO_{2max}, vVO_{2max}, vLT1 and vLT2)¹⁸. Furthermore, in order to evaluate the potential sensitivity of the SRT_{RPE} to true changes in performance, the magnitude of two component sources of variability, systematic bias and random error will need to be quantified and accounted for¹⁷.

169 170

Therefore, our study aims to investigate the construct validity of the SRT_{RPE} through association with parameters of the GXT ($\dot{V}O_{2max}$, $\dot{V}\dot{V}O_{2max}$, vLT1 and vLT2). In addition, we aim to assess the test-retest reliability of v, HR_{ex} and B[La] at each stage of the SRT_{RPE}.

175 176 177

174

METHODS

178 179

Participants.

180 Forty endurance runners (14 females: 35 ± 3 yrs; $\dot{V}O_{2max}$ 49.00 \pm 7.20ml·kg⁻¹·min⁻¹) (26 males: 38 \pm 7 yrs; $\dot{V}O_{2max}$ 57.50 \pm 181 5.63·kg⁻¹·min⁻¹) were recruited. All participants had over 2-182 years' experience of completing running-based endurance 183 184 training (> 30km per week), with at least one-year competitive 185 experience. All participants gave informed, written consent; completed a health questionnaire and confirmed that they had 186 187 been free from injury in the previous 6-months. A sub-set of eleven runners within this cohort undertook additional tests 188 189 required for reliability analysis (see **Design**) (5 females: 37 ± 8 190 yrs; VO_{2max} 50.00 ± 5.70 ml·kg⁻¹·min⁻¹5) (6 males: 35 ± 10 yrs; $\dot{V}O_{2max}$ 61.47 \pm 6.43 ml·kg⁻¹·min⁻¹). The study was approved by 191 the local University Research Ethics and Advisory Group (Prop 192 71 2017 18, Prop 107 2017 18, Prop 83 2018 19). 193

204

Design.

On their first visit all participants completed a treadmill-based maximal exercise test (GXT) to assess $\dot{V}O_{2max}$, HR_{max} and the running v at B[La] 2 mmol·L⁻¹ (vLT1) and 4 mmol·L⁻¹ (vLT2). Following 30-mins passive recovery, a familiarisation of the SRT_{RPE} was completed. On their second visit, > 2-days after and within 1-week of visit 1, participants performed the SRT_{RPE}. For analysis of reliability a subset of participants (n = 11) completed an additional visit (> 2-days and within 72-hours of visit 2) in which two trials of the SRT_{RPE} were performed, separated by 30mins passive recovery.

205 206

207 Maximal incremental run test. Participants undertook a two-phase treadmill based 208 209 (H/P/Cosmos, Nussdorf-Traunstein, Germany) GXT for the 210 assessment of vLT1 and vLT2 (Phase-one) and to determine $\dot{V}O_{2max}$, $v\dot{V}O_{2max}$ and HR_{max} (Phase-two). Before initiation of 211 the test, all participants read the standardised instructions for 212 213 reporting the RPE (6-20) scale¹². Participants completed a 5-214 min warm up at an intensity representing the v at which 215 walking transitioned to running (range 7–9 km·h⁻¹). Phase-one 216 comprised of 5–7 submaximal intervals with v increasing by 1 km·h⁻¹ every 4-mins, initiated at the v completed during warm-217 up. In the 1-min recovery between intervals, RPE (6–20)¹² was 218 219 reported and a 5µL fingertip capillary blood sample was taken to assess B[La] (Biosen C-Line, EKF Diagnostics, Penarth, 220 221 UK). Phase-one was terminated when B[La] exceeded 4 222 mmol·L⁻¹. Phase-two proceeded following a 10-min recovery; 223 initiated at the same starting v as phase-one, increasing v by 0.5

- 224 km·h⁻¹ every 1-min until volitional exhaustion. Maximal effort
- was accepted by attainment of at least two of the following
- 226 criteria: HR_{ex} within 10 beats·min⁻¹ of age-predicted maximum;
- 227 RER \geq 1.10; RPE \geq 17; and B[La] \geq 8 mmol·L⁻¹. $\dot{V}O_{2max}$ was
- determined as the highest 30-second average oxygen uptake¹⁹
- and v at this point ($\dot{V}O_{2max}$) was considered the $v\dot{V}O_{2max}$. HR_{ex}
- was recorded at a second by second frequency; Heart rate
- 231 maximum (HR_{max}) was considered the highest 5-second
- 232 average recorded HR_{ex} (Polar T31 Instruments, Kempele,
- Finland). The first and second lactate threshold (vLT1, vLT2)
- was calculated as the v at which B[La] reached 2 mmol·L⁻¹ and
- 235 4mmol·L⁻¹ respectively (Biosen C-line, EKF diagnostic,
- Barleben, Germany). Mean laboratory conditions were:
- 237 Temperature 19.2°C (range =18°C–20.2°C), Humidity 749 to
- 238 761 mmHg.

The Self-paced Submaximal Run Test (SRT_{RPE})

241 The SRT_{RPE} comprised of three, 3-min stages interspersed by 1-242 min recovery, performed on an outdoor, synthetic, 400m running 243 track (Figure 1). Intensity was prescribed by RPE 10, 13 and 17¹². Participants were instructed to control their pace based 244 upon a set of standardised instructions, which were re-read to 245 them prior to each SRT_{RPE}¹². During each 3-min stage, 246 participants v (km·h-1) and HR_{ex} (beats·min-1) were recorded 247 using a GPS monitor (1Hz sampling rate; Polar V800) and HR_{ex} 248 249 monitor (1Hz sampling rate; Polar H7). The watch-face was 250 covered during testing using a sleeve or sweat-band. A whistle 251 was blown to signify the end of each 3-min stage. The first 120seconds of v and HRex data was excluded from final analysis as 252 253 steady state has previously been established to occur after this point^{14,20}. During the 1-min recovery between stages, a 5µL 254 255 sample of whole fresh capillary blood was collected from the 256 fingertip and subsequently analysed for B[La] (Biosen C-line, EKF diagnostic, Barleben, Germany). Mean outdoor testing 257 258 conditions were: Windspeed 1.2 m/s (range = 0.4 m/s–1.8 m/s), 259 temperature 8.5 °C (range = 4°C-13°C)

Statistical Analysis

All data was assessed for normality of distribution prior to statistical analysis using the Shapiro-Wilk test. Raw data for v (km·h⁻¹), HR_{ex} (beats·min⁻¹), %HR_{max} and B[La] (mmol.L⁻¹) were summarised as mean \pm SD for each three trials. Prior to analysis, all data were log-transformed to reduce bias associated with non-uniformity of error and were subsequently backtransformed to obtain a reliability statistic in raw and percentage units. This was with the exception of %HR_{max}, where raw units are already expressed in percentage points.

A regression model, with v for each stage of the SRT_{RPE} as the independent variable and parameters of the GXT (VO_{2max}, vVO_{2max}, vLT1 and vLT2) as the dependent variable(s) was computed to examine the construct validity of the STR_{RPE}. v was selected as the only independent variable because this is the primary outcome measure of the STR_{RPE}, where intensity is fixed according to RPE. The analysis was carried out for all participants and for male and female subgroups separately. The strength of the relationships were assessed by a Pearson's product-moment correlation coefficient (r) while the shared variance was given as the coefficient of determination (R²). Standard errors of the estimate (SEE) were used to represent random bias in raw and %units (derived from analysis of the logtransformed data for %units). Uncertainty in estimates, and ranges of values compatible with the data sample, assumptions and statistical models, were expressed as 90% confidence intervals (CI)²¹. Intervals for Pearsons r and SEE values were derived from an F and chi-squared distributions, respectively. The strength of correlations were determined using the following criteria: 0.1 (trivial), 0.1–0.3 (small), 0.3–0.5 (moderate), 0.5– 0.7 (large), 0.7–0.9 (very large), and 0.9–1.0 (almost perfect)¹⁰. Analysis was performed using Microsoft Excel (Version 16.28, Microsoft, Redmond, WA, USA), using a spreadsheet downloaded from (sportsci.org/2015/ValidRely.htm).

To examine the re-test reliability of STR_{RPE}, the systematic change in each outcome measure was given as the mean difference between consecutive trials. A minimum effect test (MET) provided a practical, probabilistic interpretation of the mean change in each outcome measure between trial 1-2 and 2-3²⁴. For v and internal load measures (HR_{ex} and B[La]), we used a smallest important threshold of 0.2 multiplied by the pooled, between-subject SD of all three trials, alpha set at $P_{\rm MET}$ <0.05. Typical error (TE, also expressed as a coefficient of variation [CV]) was also calculated between consecutive trials, estimated as the standard deviation of change scores divided by the square root of 2. These values were then pooled to give the overall TE and CV. In addition, Intraclass correlation coefficients (ICC_{3.1}) was assessed using a 2-way mixed-effects model 22. Confidence intervals for the mean change were calculated using a tdistribution. For TE, CI were calculated using the chi-squared distribution and for the ICC_{3.1} an F-distribution was used²³. The thresholds for interpretation of the magnitude of ICC_{3,1} were : >0.99 (extremely high), 0.90–0.99 (very high), 0.75–0.90 (high), 0.50–0.75 (moderate), 0.20-0.50 (low), < 0.20 (very low)²⁵. Analysis was performed using Microsoft Excel (Version 16.28, Microsoft, Redmond, WA, USA), using a spreadsheet downloaded from (sportsci.org/2015/ValidRely.htm).

Group performance in GXT and SRT_{RPE}.

326 Table 1 displays the mean \pm SD results for the GXT for both 327 male and female participants. Table 2 displays the physiological responses (HR_{ex}, %HR_{max} and B[La]) and v associated with each 328 329 stage of the SRT_{RPE}. Each stage was considered sub-maximal 330 based upon prior outlined criterion for maximal effort (see 331 Maximal incremental run test), with intensity prescribed by 332 RPE 10, 13 and 17 corresponding to; $74.7 \pm 6.3\%$, $81.4 \pm 7.0\%$ 333 and $88.7 \pm 6.1\%$ of HR_{max} and 1.5 ± 0.4 mmol.L⁻¹, 1.8 ± 0.6 mmol.L⁻¹ and 3.5 ± 1.6 mmol.L⁻¹ respectively. As shown in 334 Figure 2, the mean absolute difference (km·h⁻¹) between vLT2 335 evaluated by GXT and v at each stage of the SRT_{RPE} was; -336 337 $2.51\pm1.58 \text{ km}\cdot\text{h}^{-1}$ for RPE 10, $-0.34\pm1.52 \text{ km}\cdot\text{h}^{-1}$ for RPE 13 and $1.53 \pm 1.40 \text{ km} \cdot \text{h}^{-1}$ for RPE 17. 338

347

Concurrent validity of the SRT_{RPE} .

Table 3 and Figure 3 display the inferential validity statistics for parameters of the SRT_{RPE} with parameters of the GXT ($\dot{V}O_{2max}$, $v\dot{V}O_{2max}$, vLT1 and vLT2). For all participants (n = 40), RPE 17 had the strongest association with parameters of the GXT (r range = 0.60-0.66, large). Standard errors of the estimate were ~8–12% for all measures. Table 3 shows the relationship between v at each stage of the SRT_{RPE} and parameters of the GXT for each sex.

348 349 350

351

352

353

354

Test-retest reliability of the SRT_{RPE} .

Table 2 displays the inferential statistics for the test-retest reliability of the SRT_{RPE}. The MET revealed no meaningfully changes in v, HR_{ex}, %HR_{max} and B[La] between trial 1–2 and 2– 3 ($P_{\text{MET}} > 0.05$). Figure 4 illustrates individual values for v in trial 1, 2 and 3 for each SRT_{RPE} intensity.

355 356

357 CV's for v ranged from 3.9%-5.5%, and from 2.5%-5.6% for HRex, with variation consistently lower at greater submaximal 358 intensities. The typical error for %HR $_{max}$ ranged 2.2%–4.0%. 359 360 B[La] displayed the highest CVs' ranging from 24.8–28.6%. $ICC_{3.1}$'s were moderate to high for parameters v (range = 0.76– 361 362 0.84), HR_{ex} (0.72–0.92) and % HR_{max} (0.64–0.89) at all stages of 363 the SRT_{RPE}. B[La] displayed the lowest ICC_{3.1} (0.26–0.69).

364

DISCUSSION.

365 366 Our study sought to assess the construct validity and reliability 367 of parameters of the novel SRT_{RPE}. Results showed large associations (r range = 0.50-0.66) between v at each stage of the 368 369 SRT_{RPE} and parameters of the GTX, suggesting results of the SRT_{RPE} can validly reflect an individuals' level of aerobic 370 fitness. A moderate to high reliability for parameters: v (ICC 371

range = 0.76–0.84), HR_{ex} (0.72–0.92) and %HR_{max} (0.64–0.89) was measured during self-paced, submaximal efforts.

The v at RPE 10, 13 and 17 showed large associations with $v\dot{V}O_{2max}$ (r = 0.50–0.66) and vLT2 (r = 0.50–0.62) (Table 2); suggesting SRT_{RPE} is able to discriminate between individuals of varying aerobic fitness. Previous authors have described greater associations between LSCT and GXT parameters⁹, which may result from their use of standardised, laboratory conditions. However, Vesterinen¹⁰ showed the v at intensities 60%, 80% and 90% HR_{max} recorded in outdoor conditions, still displayed greater correlations with $v\dot{V}O_{2max}$ (r range = 0.74– 0.83) and vLT2 (0.78–0.89) than the current study. This discrepancy may result from differing methods of assessments of vVO_{2max} and vLT2 between studies, or disparity in the duration in intervals of the GXT (4-mins) and SRT_{RPE} (3-mins) analysed in the current study. We cannot comment if greater error in the SRT_{RPE} caused lower associations as the reliability of the submaximal exercise test used by Vesterinen¹⁰ was not reported.

The analysis of the regression error (SEE) shows for example, for a given vRPE 17 the associated $\dot{V}O_{2max}$ may vary by 9.0% (7.6–11.3%) and vLT2 by 10.0% (8.3–12.5%). The magnitude of this error is greater than previously identified meaningful differences for both $\dot{V}O_{2max}^4$ and vLT2²⁶, suggesting that v measured during the SRT_{RPE} would not accurately predict the treadmill based GXT results.

Our results show that when separated, female participants displayed greater associations between our independent and dependent variables resulting from lower values of v in SRT_{RPE} and GXT parameters, when compared to males who 'clustered' higher on both (Table 3, Figure 3). These results highlight the potential constraints in generalising overall correlation results to more homogeneous subsets (e.g. elite cohorts)¹⁷. In addition, our results provide further evidence that runners homogeneous in $\dot{V}O_{2max}$ show variability in performance v, explaining the low association between $\dot{V}O_{2max}$ and endurance performance in such cohorts^{5,6} and support the preferential use of field-based exercise tests for monitoring⁶.

Our results support previous evidence that RPE 10, 13 and 17 correspond to intensities below, approximately at, or above vLT2 (Figure 2)^{11,13}. Of the 40 participants, only one regulated vRPE 10 above their vLT2 (+0.43 km·h⁻¹) and 3 participants regulated vRPE 17 below their vLT2 (each -0.90, -0.64 and -0.23 km·h⁻¹ below vLT2). This standardisation of intensity may aid the interpretation of responses to endurance training

interventions which specifically target adaptations around these metabolic thresholds.

Results revealed no meaningful difference for v, HR_{ex}, %HR_{max} and B[La] between trials 1-2 and 2-3 ($P_{\text{MET}} > 0.05$) providing no evidence of systematic bias¹⁷. The study may be limited in performing two trials (2-3) on the same day²³. However, evidence of low variability between trials 2-3 suggests that the SRT_{RPE} can reliably be used multiple times within a day which may benefit monitoring of responses to morning and evening training. The relative reliability of v during SRT_{RPE} is comparable to previous research describing the variability in 2mins track-based v (km·h⁻¹) produced at RPE 10 (6.4% \pm 3.1%), RPE 13 (2.9% \pm 1.1%) and RPE 17 (2.9% \pm 0.8%)¹⁵. Together our results suggest that 3-mins is sufficient in allowing participants to reach and maintain a steady state v14 based on RPE; minimising the time required for testing compared to similar submaximal protocols (i.e. ~6-mins less versus LSCT).

447

448

449

Field-based maximal exercise tests such as distance fixed timetrials are often preferred for athlete monitoring due to their high ecological validity and reliability^{6,16}. Previously, the average v for maximal effort 1500m and 5km time-trials have displayed CV's of 2.0% (95% CI: 1.2-4.0%) and 3.3% (95% CI: 2.1-6.8%) respectively²⁷. As such, the within-individual variability of vRPE 17 seen during the current study is comparible (CV = 3.9%, 90% CI: 3.0-5.7%). This provides evidence that the SRT_{RPE}, which provides a more time-efficient and less physically demanding alternative to maximal performance tests, is also comparable in sensitivity.

453

454

455 456

457

458

459 460

461

The potential sensitivity of the SRT_{RPE} can be explored by comparing the magnitude of measurement error in the test (noise) to prior reported meaningful changes in these parameters (signal)^{17,23}. Previous literature, assessing a comparable cohort, reported 5.1% improvement in average v over 5000m, on an outdoor track following 6-weeks of endurance training. Treadmill based submaximal v (vLT2) has similarly been shown to vary by 4.4–6.3% following 6-week's training^{3,4}. This magnitude of expected change (signal) is greater than the CV (noise) for v at all stages of the SRT_{RPE}, suggesting an acceptable sensitivity of the test^{15,22}.

462 463 464

465

466 467

468

469

The utility of HR_{ex} to sensitively monitor aerobic fitness has been debated due to its sensitivity to confounding variables outside of training stress²⁰. Previous research has shown a dayto-day variation in HR_{ex} of 6-8 beats·min⁻¹ at intensities 60-80% maximal and 3-5 beats·min⁻¹ at intensities 80-90% of maximal²⁸. This is comparable to the random error found in the current study (Table 2). Additionally, previous research reported

471 a comparable magnitude of variability (CV range = 2.3-7.0%) in 472 % HR_{max} during self-paced combined arm and leg cycling at RPE 9, 13 and 17²⁹. The variability shown in the current study should 473 474 be accounted for when determining true-change in this parameter. The measurement error was greatest for B[La] with a 475 CV range of 24.8–28.6%. This high magnitude of variation has 476 477 similarly been reported between repeated 1000m efforts at RPE 17 (CV = 16.8%)³⁰. Our results suggest that B[La] during the 478 SRT_{RPE} may be too unreliable for monitoring purposes. 479

480 481

482

483

484

485

486

Future research aiming to monitor individual's responses using the SRT_{RPE} should be cautious that results may be influenced by environmental conditions and reliability of the GPS and HRex monitors used. It would be advised to complete a separate reliability analysis if conditions or equipment vary from those used in the current study.

491

492 493

496

497

498 499

500

501

PRACTICAL APPLICATIONS:

Large between-subject correlations between v at each RPE stage and GXT suggest that these measures are convergent of a similar fitness construct (aerobic capacity) and the STR_{RPE} could therefore be a more

494 accessible and practical test to discriminate between 495 participants.

Modest error between v at each RPE stage and GTX parameters suggests the SRT_{RPE} should be used cautiously to predict GXT variables such as vLT2 and warrants further investigation for this use.

Low TE/CV's for v selected at each RPE intensity, suggest that true individual changes can be detected with reasonable accuracy.

502 503 504

505 506

507 508

509

CONCLUSIONS:

The novel SRT_{RPE} shows large associations with GXT parameters, suggestive of construct validity. The SRT_{RPE} test shows acceptable reliability over repeated trials. Future research should examine response to the SRT_{RPE} across participants with a broader range of aerobic capacities and its sensitivity to withinindividual changes in fitness.
