Huntington's disease is a neurodegenerative disorder caused by CAG expansions in the huntingtin (*HTT*) gene. Modelling Huntington's disease is challenging, as rodent and cellular models poorly recapitulate the disease as seen in ageing humans. To address this, we generated induced neurons through direct reprogramming of human skin fibroblasts, which retain age-dependent epigenetic characteristics.

Huntington's disease induced neurons (HD-iNs) displayed profound deficits in autophagy, characterized by reduced transport of late autophagic structures from the neurites to the soma. These neurite-specific alterations in autophagy resulted in shorter, thinner and fewer neurites specifically in HD-iNs. CRISPRi-mediated silencing of *HTT* did not rescue this phenotype but rather resulted in additional autophagy alterations in control induced neurons, highlighting the importance of wild-type *HTT* in normal neuronal autophagy.

In summary, our work identifies a distinct subcellular autophagy impairment in adult patient derived Huntington's disease neurons and provides a new rationale for future development of autophagy activation therapies.

Introduction

Huntington's disease is an autosomal dominant neurodegenerative disorder caused by an expanded polyglutamine tract within the first exon of Huntingtin (*HTT*).¹ Clinically, Huntington's disease is characterized by involuntary movements together with cognitive impairment, psychiatric disturbances as well as metabolic and sleep problems, a result of extensive cell impairment and death within the CNS. Genetics and age in combination are key components of Huntington's disease pathology as the length of the CAG repeat expansion in *HTT* correlates with age of disease onset, and manifest disease is more prevalent with increasing age, independent of CAG repeat length.^{1–3} Most Huntington's disease patients have CAG repeats in the range of 40–45 CAGs and are diagnosed around the age of 50.⁴ *HTT* is ubiquitously expressed, yet the presence of a mutated Huntingtin allele (m*HTT*) results, at least early on, in the dysfunction and death of neurons specifically in the striatum and cortex.⁵ Mutant *HTT* has a propensity to aggregate and form insoluble protein inclusions, but it is still debated as to how protein aggregation influences, if at all, neuronal dysfunction and ultimately cell death. In general, the molecular and cellular basis for the pathology and the age-related disease process remains poorly understood and thus the development of disease-modifying treatments for Huntington's disease remains a major challenge.

Several studies have documented altered autophagy in neurodegenerative disorders including Huntington's disease, a phenomenon thought to contribute to the failure of clearance of aggregating proteins.^{6–12} Autophagy is a lysosomal protein degradation pathway that is present at a basal level in all cells, including neurons and is essential for their survival.^{13,14} Boosting autophagy through pharmacological or genetic manipulation successfully reverses disease-associated phenotypes in various mouse models of neurodegenerative disorders, including models of Huntington's disease, and is associated with a reduction of the protein aggregate burden.^{6,7,11,15,16} These preclinical findings have led to the initiation of clinical trials to activate autophagy in Huntington's disease and other neurodegenerative disorders.^{17–20} While these initial studies have shown that this approach is feasible and well tolerated, it is also evident that therapeutic approaches to activate autophagy need to be optimized and tailored for different neurodegenerative disorders. In particular, a clear understanding of exactly how and why alterations in autophagy appear in Huntington's disease (and other neurodegenerative disorders) and how this contributes to neuronal dysfunction and death is currently lacking.

In this study we have used direct reprogramming of human fibroblasts to generate patient-derived induced neurons (iNs) that retain age-associated epigenetic marks.^{21–23} When performing a combined transcriptomic, proteomic and automated microscopic analysis on induced neurons obtained from patients with Huntington's disease (HD-iNs), we found a clear impairment in autophagy that was characterized by a failure to transport late autophagic structures from neurites to the cell body. This

subcellular autophagy impairment was directly linked to a reduction in the neurite complexity of HD-iNs. The autophagy impairment in Huntington's disease neurons also appeared without the presence of m*HTT*-aggregates, demonstrating that this phenomenon lies upstream of overt protein aggregation. Finally, inhibition of *HTT* expression (both wild-type and mutant) using CRISPR interference (CRISPRi) rescued some of the autophagy-related impairments but also resulted in additional new autophagy alterations suggesting that the disease phenotype is driven by a combination of both loss-of-function and gain-of-function mechanisms. In summary, our results provide a novel understanding of the Huntington's disease process by demonstrating a specific subcellular autophagy impairment localised to the neurites. Our findings have clear translational implications.

Materials and methods

Human tissue

Post-mortem human brain tissue was obtained from the Cambridge Brain Bank (Cambridge, UK) and used under local ethics approval (REC 01/177). Severity of Huntington's disease was graded by a certified pathologist according to the Vonsattel grading system²⁴ (Table 1).

Cell culture

Adult dermal fibroblasts were obtained from the Huntington's disease clinic at the John van Geest Centre for Brain Repair (Cambridge, UK) and the Fondazione IRCCS, Istituto Neurologico Carlo Besta (Milan, Italy) and used under local ethical approvals (REC 09/H0311/88). The cells were obtained from 10 Huntington's disease and 10 non-related healthy individuals (Table 2) (for more information on the biopsy sampling see Drouin-Ouellet et al.²¹). CAG repeat length was defined for both alleles using Sanger sequencing (Laragen Sanger Sequencing Services). The fibroblasts were kept in Dulbecco's modified Eagle medium (DMEM) glutamax medium (Gibco) supplemented with 10% foetal bovine serum (FBS) (Gibco) and 1% penicillin/streptomycin (Gibco) and passaged when

Overview of the cohort used in the study specifying the age, sex, CAG repeats and age at onset of 10 healthy control (C) and 10 Huntington's disease (HD) patient fibroblasts lines. n/a = not available.

^aAge of the fibroblasts indicates when they were collected.

^bAge at onset correspond to appearance of motor symptoms.

they reached 80–90% confluency using a previously described procedure.²¹

Lentiviral production

Third-generation lentiviral vectors were produced as previously described.⁶

For induced neuron conversion LV.U6.shREST1.U6.shREST2.hPGK.BRN2.hPGK.Ascl1.WPRE transfer vector was used. This previously published and available construct from the plasmid repository contains the transcription factors ASCL1 and BRN2 with two short hairpin RNAs (shRNA) targeting REST.²¹ The lentiviral vector also contains non-regulated ubiquitous phosphoglycerate kinase (PGK) promoters and a Woodchuck Hepatitis Virus (WHP) Posttranscriptional Regulatory Element (WPRE). Four additional viral vector plasmids were used: pLV.hU6-sgLacZ-hUbc-dCas9-KRAB-T2a-GFP (*LacZ*), pLV.hU6-sg1HTT-hUbc-dCas9-KRAB-T2a-GFP (*g1HTT*), pLV.hU6-sg2HTT-hUbc-dCas9-KRAB-T2a-GFP (*g2HTT*) and pLV.hU6-sg3HTT-hUbc-dCas9-KRAB-T2a-GFP (*g3HTT*). Vectors are specified in the CRISPRi section below.

Virus titration was performed, and the titre was determined with qRT-PCR as previously described.⁶ The virus titres ranged between 2.33×10^8 and 9.3×10^9 . A multiplicity of infection (MOI) of 1–20 was used from different lentiviral vectors as specified for each case.

Neural conversion

Prior to the start of conversion, Nunc Delta surface treated plates (Thermo Scientific) were coated as previously described.²⁵ Fibroblasts were plated at a density of 50 000 cells per Nunc 24-well (~26 000 cells/cm²) in fibroblast medium 1 day prior to the

start of conversion. On the following day (Day 0), the fibroblasts were transduced with the all-in-one lentiviral vector at MOI 20. The conversion was performed as previously described until the cells were harvested for experiments on Day 25, 28 or 50 of conversion as described below.²¹

CRISPRi

To silence the transcription of *HTT* we used the catalytically inactive dead Cas9 (dCas9) fused to the transcriptional repressor KRAB in six control (1, 2, 4, 6, 8 and 10) and six Huntington's disease (1, 2, 5, 6, 9 and 10) cell lines, and only including those Huntington's disease lines with the shorter CAG-repeats.^{26,27} Single guide sequences were designed to recognize DNA regions just downstream of the *HTT* transcription start site (TSS at 3074690 using reference sequence NC_000004.12) according to <https://portals.broadinstitute.org/gpp/public/analysis-tools/sgRNA-design-crisprai?mechanism=CRISPRiAlgorithms> (Supplementary Table 1).

The guides were inserted into a deadCas9-KRAB-T2A-GFP lentiviral backbone containing both the guide RNA under the U6 promoter and dead-Cas9-KRAB and GFP under the Ubiquitin C promoter [pLV.hU6-sgRNA-hUbc-dCas9-KRAB-T2a-GFP was a gift from Charles Gersbach (Addgene plasmid #71237; <http://n2t.net/addgene:71237>; RRID:Addgene_71237)]. The guides were inserted into the backbone using annealed oligos and the BsmBI cloning site. Lentiviruses were produced as described above yielding titres between 4.9×10^8 and 9.3×10^9 . Three guides were designed and tested in HEK293T and induced pluripotent stem cells (iPSCs). HEK293T cells were cultured similarly to the fibroblasts cells as described above. iPSCs (RBRC-HPS0328, 606A1 from RIKEN) were cultured as previously described.²⁸ HEK293T and iPSCs were transduced with different gRNAs targeting *LacZ* or *HTT*. After 4 days of transduction, cells were passaged and 7 days post infection GFP⁺PI⁻ cells were purified by FACS. Silencing efficiency was tested using quantitative real-time PCR and two gRNAs were chosen for further analysis.

Guide 2 and Guide 3 were chosen for further validation with 'cut-sites' at 25 bp and 65 bp downstream of the transcription start site, respectively. Control *LacZ* virus with a gRNA sequence not present in the human genome was also produced and used in all experiments. All lentiviral vectors were used with MOI of 20. Cells were FACS sorted one week after transduction and silencing efficiency was validated using standard quantitative real-time reverse transcriptase PCR techniques as described below.

Autophagy treatments

Six Ctrl (1, 2, 4, 6, 8, 10) and six Huntington's disease (1, 2, 5, 6, 9, 10) cell lines, which only included those Huntington's disease lines with the shorter CAG-repeats, were treated with factors regulating autophagy as follows. The cell medium was aspirated from the wells and fresh medium with one of the factors (Bafilomycin, 200 nM, Merck Millipore; Rapamycin, 20 nM, Sigma-Aldrich; Wortmannin, 100 nM, Sigma-Aldrich) was added to the well followed by fixation for immunocytochemistry after 4 h. Torin (250 nM, Tocris Bioscience) treatment was performed identically and only lasted for 2 h. Non-treated wells received fresh media with dimethyl sulphoxide (DMSO) in equivalent amount to that used in treated cells.

Cells were starved by replacing the media with Hank's Balanced Salt Solution (Thermo Fisher, 14025092) for 2 h before fixation.

Immunostaining

Immunocytochemistry to stain induced neurons was performed as previously described.²¹ Briefly, the cells were fixed with 4% paraformaldehyde for 10–15 min. Following fixation, the paraformaldehyde was aspirated, and the cells were washed carefully twice with DPBS. Thereafter, the cells were permeabilized in 0.1 M phosphate-buffered saline (PBS) with 0.1% Triton X-100 for 10 min and then blocked for a minimum of 30 min in a blocking solution of 0.1 M PBS and 5% normal donkey serum. The primary antibodies were diluted in blocking solution and incubated overnight at 4°C (Supplementary Table 2). The cells were washed twice with DPBS and the secondary antibody conjugated to a fluorophore (Supplementary Table 2) diluted in blocking solution and incubated for 2 h at room temperature. Following incubation with the secondary antibodies, DAPI was applied for 15 min and the cells were washed once with DPBS. Finally, high-content automated microscopy analysis was performed using the Cellomics Array Scanner (VT1 HCS Reader, Thermo Fischer) and imaging was performed using either a Leica inverted fluorescent microscope (model DMI6000 B) or a Leica TCS SP8 confocal laser scanning microscope.

Immunohistochemistry staining was performed as described previously.⁶ Paraffin-embedded striatal sections (10- μ m thick) were taken from three differently graded Huntington's disease patients and healthy age-matched control brains. Sections were stained using the antibodies listed in Supplementary Table 2, using mouse anti-Neurofilament and rabbit anti-p62. Briefly, sections were surrounded with Dakopen and dried for 10 min at 65°C. Sections were then further incubated first with xylene and then with different concentrations of ethanol (99.5%, 95%, 70%), MilliQ water and last in TN buffer (1 M Tris-HCl, 1.5 M NaCl, MilliQ water) prior to 20 min of boiling in a pH=9 Tris/EDTA solution. After cooling, the sections were again twice incubated with TN buffer and then with TN+5% serum at room temperature. The sections were incubated at room temperature with the primary antibody diluted in TNT+5% serum (TN+10% Tween20). Secondary antibodies were diluted in TNT+5% serum and kept in the dark for 2 h after washing with TN and TNT. Lastly, sections were washed, and cover-slipped with PVDA-DABCO with DAPI. All fluorescent images were taken using a Leica TCS SP8 confocal laser scanning microscope.

High-content automated microscopy

The Cellomics Array Scan (VT1 HCS Reader, Thermo Fischer) was used for high-content automated microscopy.

To quantify the number of DAPI⁺, MAP2⁺, and TAU⁺ cells and define neuronal purity and conversion efficiency 'target activation' (TA) was used. Using this method, we obtained objective, unbiased measurements of the induced neuronal cultures. The TA program was used to acquire images of 100–289 fields using a 10 \times objective of each well to define cell number, neural purity and conversion efficiency. Wells with <50 valid fields were excluded from further analysis. The program defined DAPI⁺ cells based on intensity and area and then measured fluorescent intensity on a cell-by-cell basis to identify MAP2⁺ and TAU⁺ cells. We excluded DAPI cells which were clumped together or where the separation of nuclei by the software was not efficient enough by setting a maximum area and shape to be able to ensure that we were counting single cells. Border objects were also excluded from the analysis. TAU or MAP2 positive cells were identified by setting a threshold defined by total cell body intensity and average cell body intensities with

only one valid nucleus. The neuronal purity was quantified as the fraction of MAP2⁺ or TAU⁺ cells of the total DAPI⁺ cells at the time of analysis. The conversion efficiency was determined as the number of MAP2⁺/TAU⁺ cells over the number of fibroblasts plated at the start of conversion.

The 'neuronal profiling' (NP) program was used at a 10 \times objective. NP analysis was performed by re-analysing images taken for the TA analysis to quantify the neuronal morphology of the MAP2⁺ and TAU⁺ cells. Control and HD-iNs were imaged with a 10 \times objective after 50 days of conversion. The NP program was used to acquire images of 100–289 fields at \times 10 magnification of each well to define neuronal morphology. Wells with <50 valid fields were excluded from further analysis. First valid nuclei were defined by DAPI staining based on intensity and area. Border objects were excluded from the analysis. Average cell body area, average neurite area, average number of neurites, average neurite length, average neurite width and average number of branchpoints per cell was defined by the NP program based on MAP2 or TAU neuronal staining. Border objects were excluded from further analysis.

Neuronal profiling with spot detection (using a 20 \times objective) was used to determine average LC3B, LAMP1 and p62 dot number and size per cell within MAP2⁺ or TAU⁺ cell bodies and neurites. LAMP1 and LC3B co-localization was also analysed by defining the overlapping area as a percentage between the two markers. First valid nuclei were defined by DAPI staining based on intensity, area, and shape. Border objects were excluded from further analysis. Next, cell bodies and neurites were defined based on total and average intensity and area of MAP2⁺ or TAU⁺ as the region of interest. Border objects were excluded from further analysis here also. Autophagy markers were analysed and defined by intensity and area within the valid neuronal cells. In every case, 150–250 fields were analysed and wells <50 valid fields were excluded from further analysis.

In each case we have verified the accuracy of the program by manually curating 10 images from each conversion round to ensure that the thresholds were set accurately to define the neuronal population and the 'dots'.

Fluorescence-activated cell sorting

To increase the purity of converted control and HD-iNs for RNA-sequencing, the cells were harvested and sorted by fluorescence-activated cell sorting (FACS), as previously described.²⁵ To this end, the cells were dissociated with StemPro accutase by incubation at 37°C for approximately 10–15 min. Following detachment, the cells were washed off and collected in FACS buffer [Hanks' Balanced Salt solution (HBSS) with 1% bovine serum albumin (BSA) and 0.05% DNase I (Sigma)] and centrifuged at 400g for 5 min. The supernatant was aspirated, and the cells were once more washed in FACS buffer, centrifuged, and resuspended in 50 μ l FACS buffer. An allophycocyanin conjugated antibody against human NCAM (1:10, anti-mouse hNCAM, Biosciences, #555515, clone B159) was added to the samples and incubated for 15 min on the bench. The antibody was washed twice with FACS buffer and centrifuged again with the same settings. After the final dilution, 1:1000 propidium iodide (Sigma) was added to label dying cells. The cells were sorted with a FACSAria III through a 100 μ m nozzle, using a 1.5 filter and area scaling of 0.35. Gates were set up to obtain small NCAM⁺PI⁻ cells using fluorophore specific gates and the forward and side scatter to select the smaller cell population. Re-analysis was also performed for each sorted sample and a purity >95% was set as a cut-off. In each case 10 000 NCAM⁺PI⁻

single cells were sorted at 10°C and the samples were then kept on ice for further processing. Sorted cells were centrifuged at 400g for 5 min and after the removal of the supernatant, frozen on dry ice and stored for RNA-sequencing experiments.

To purify successfully transduced GFP⁺ HEK293T, iPSCs or fibroblasts, these cells were also harvested and sorted by FACS. Untransduced and transduced cells after 1 week of lentiviral transduction were dissociated with 0.05% trypsin (Sigma) for 5 min at 37°C. Following detachment, the cells were washed off and collected in FACS buffer and centrifuged at 400g for 5 min. Supernatant was removed and cells were washed with a FACS buffer again. After washing cells were filtered through a 60 µm sterile nylon filter to remove possible cell aggregates and collected in 500 µl FACS solution. Before sorting, cells were stained with propidium iodide. GFP⁺PI⁻ cells were sorted into fresh DMEM medium for further analysis. In all cases untransduced cells were also FACS sorted. Re-analysis was also performed for each sorted sample and a purity >95% was set as a cut-off.

Quantitative real-time PCR

To measure the expression level of *HTT* RNA and to detect intron retention in fibroblasts and induced neurons from healthy control subjects and Huntington's disease patients, we did qRT-PCR analysis. Total RNA was first extracted according to the supplier's recommendations using the mini or micro RNeasy kit (Qiagen). cDNA was generated using the Maxima First Strand cDNA Synthesis Kit. All primers were used together with LightCycler 480 SYBR Green I Master (Roche). Three reference genes were used for each qRT-PCR analysis (*ACTB*, *GAPDH* and *HPRT*). Sequences were:

ACTB,

fw: CCTTGCACATGCCGG

rev: GCACAGAGCCTCGCC

GAPDH

fw: TTGAGGTCAATGAAG

rev: GAAGGTGAAGGTCCG

HPRT

fw: ACCCTTTCCAAATCCTCAGC

rev: GTTATGGCGACCCGACG.

HTT expression levels were tested using two alternative primer pairs. Sequences were:

HTT-pp1

fw: TCAGCTACCAAGAAAGACCGT

rev: TTCCATAGCGATGCCAGAA

HTT-pp2

fw: TCAGAAATGCAGGCCTTACCT

rev: CCTGGACTGATTCTTCGGGT.

Intron retention was tested using exon 1–exon 2 and exon 1–intron 1 primer pairs. Sequences were:

HTT-exon 1–intron 1

fw: CACCGACCGTGAGTTTGGG

rev: CAGGCTGCAGGGTTACCG

HTT-exon 1–exon 2

fw: CTGTGGCTGAGGAGCCG

rev: TGTCAGACAATGATTCACACGG.

In all cases data were quantified using the $\Delta\Delta C_t$ method.

Western blot

Fibroblasts (200 000 cells/ sample) and induced neurons (converted in T25 flasks starting from 250 000 fibroblasts/ sample or converted

in Nunc Delta treated 6-well plates starting from 200 000 plated fibroblasts/ sample) were harvested as follows: the cell medium was removed and the cells were lysed in RIPA buffer (Sigma) with 4% protease inhibitor cocktail (PIC, cOmplete™). For autophagy flux measurements induced neurons were treated with Bafilomycin (200 nM, Merck Millipore) for 4 h, while non-treated wells received fresh media with DMSO in an equivalent amount to that used in treated cells before harvesting. The lysed cells were collected in a microcentrifuge tube and incubated on ice for a minimum of 30 min, followed by centrifugation at 10 000g for 10 min in 4°C to pellet cellular debris. Following centrifugation, the supernatant was transferred to new vials. The protein content was quantified with Bradford DC™ Protein Assay (Bio-Rad) and 10–15 µg protein of each sample was used for loading the gel. Gel electrophoresis and blotting was performed as previously described.⁷ Both the primary and secondary antibodies (Supplementary Table 3) were diluted in milk blocking solution. The blots were incubated in Immobilon Western Chemiluminescent HRP Substrate (Millipore) for 5 min to enhance the signal for visualization using the ChemiDoc™ MP Imaging System.

To determine *HTT* protein expression in fibroblasts and induced neurons protein concentration was determined using Bradford Protein Assay (Bio-Rad Laboratories). *HTT* immunoblotting was performed as previously described.²⁹ Briefly, proteins were loaded on a Tris-acetate gradient gel (3–10% 37.5:1 acrylamide/Bis-acrylamide, BioShop), migrated at 100 V and transferred in Bicine/Bis-Tris transfer buffer overnight at 25 V and 4°C, followed by 1 h at 90 V. Membranes were blocked with 5% milk and 1% BSA in Tris-buffered saline with 0.1% Tween 20. Membranes were then incubated with primary antibodies raised against poly-glutamine repeats (5TF1-1C2, EMD millipore) or *HTT* (1HU-4C8 and mEM48, both from EMD Millipore; CH00146, CHDI – Corriell Institute). Detection was achieved using appropriate horseradish peroxidase-labelled secondary antibodies and Immobilon western chemiluminescent HRP substrate (Millipore Sigma). Band intensity was determined with ImageJ 2.0.0-rc-69/1.52p software (<http://imagej.nih.gov/ij>) and corrected to the total amount of protein per lane.

RNA preparation and sequencing

Samples C1–C7 (four males and three females) and Patients HD1–2, HD5–7 and HD9–10 (age-matched but only males, only including Huntington's disease lines with the shorter CAG-repeats) were used for RNA-sequencing. Total RNA was extracted from 10 000 cells/sample with the RNeasy micro kit (Qiagen) according to the manufacturer's protocol. A quality control of the samples was made with the Bioanalyzer RNA pico kit. cDNA was synthesized with the SMART-Seq® v4 Ultra® Low Input RNA Kit for Sequencing (Takara/Clontech) and assessed with the Bioanalyzer high sensitivity DNA kit, followed by library preparation using Nextera XT (Illumina). The quality and concentration of the libraries was assessed with the Bioanalyzer high sensitivity DNA kit and Qubit dsDNA BR DNA assay kit, respectively. Paired-end sequencing of 2 × 150 base pairs (300 cycles) was done with a NextSeq 500/550 High Output v2.5 kit 400 million reads (Illumina) on a NextSeq 500 sequencer (Illumina).

RNA sequencing analysis

Fibroblast and induced neuron samples were sequenced as specified above for further analysis. Raw base counts were demultiplexed and converted to sample-specific fastq format files using

Figure 1 Huntington’s disease fibroblasts readily convert into induced neurons with similar purity and conversion efficiency. (A) Experimental overview of the induced neuron (iN) conversion. (B) Induced neurons derived from control and Huntington’s disease patient fibroblasts both

(Continued)

the bcl2fastq program (Illumina) with default parameters. The quality of the reads was assessed using FastQC (<https://www.bioinformatics.babraham.ac.uk/projects/fastqc/>) and MultiQC (<https://multiqc.info/>), after which reads were mapped to the human genome (GRCh38) using the STAR mapping algorithm with default parameters.³⁰

Indexing was performed to investigate whether incomplete transcripts were generated with the samtools (version 1.4) index, and the bigwig files to generate the IGV tracks (version 2.10.0, assembly hg38) were produced using bamCoverage from deeptools (version 2.5.4) normalizing for sequencing depth using `normalizeUsingRPKM`.

Following mapping, mRNA expression was quantified using FeatureCounts. Only reads mapping to genetic elements annotated as exons were quantified, and only the primary alignments were included.³¹ The GTF annotation file used for the quantification was downloaded from Gencode version 30 (<https://www.gencodegenes.org/human/>). We performed median of ratios normalization with DESeq2³² to account for differences in sequencing depth and RNA composition. Gene ontology overrepresentation tests were performed using PANTHER database (version 14). The GO analysis between induced neurons and fibroblasts was performed using the up and downregulated genes found to be significantly different using DESeq2. Genes with $\text{basemean} > 10$ were used as the background set for the overrepresentation test, and only significant terms are shown ($\text{Padj} < 0.05, \log_2\text{FC} > 1$).

Using the normalized reads (mean of ratios calculated with DESeq2), we tested for difference in expression between HD- and Ctrl-iNs using unpaired t-test. We defined significantly different genes those with $P\text{-value} < 0.05$. Code for tests and visualization is available at Github (https://github.com/raquelgarza/iN_HD).³² Gene ontology overrepresentation tests comparing HD- and Ctrl-iNs using the RNA sequencing data (gene sets of up and downregulated defined as $\text{Padj} < 0.05, \log_2\text{FC} > 0$) were performed using PANTHER (version 16) using Fisher's exact test and Benjamini-Hochberg correction to calculate false discovery rates.³³ All genes with some expression in any of the conditions were used as background sets for these tests.

Shotgun proteomic analysis

Samples C1–C7 (four males and three females) and Patients HD1–2, HD5–7 and HD9–10 (age-matched but only males, only including

Huntington's disease lines with the shorter CAG-repeats) were used for mass spectrometry (MS) analysis. Fibroblasts (500 000 cells) and induced neurons converted in T75 flasks (600 000 fibroblasts plated for conversion per sample) were dissociated as previously described and prepared for quantitative proteomic analysis as follows. The cells were carefully washed off and collected in a tube with either trypsin or accutase and spun at 400g for 5 min. The supernatant was discarded, and the pellets were washed three times with DPBS. After the final wash, the supernatant was aspirated, and the pellets were frozen on dry ice and stored at -80°C until use.

The cell pellets were resuspended in 200 μl lysis buffer (50 mM DTT, 2% SDS, 100 mM Tris pH = 8.6), rested for 1 min on ice and sonicated (20 cycles: 15 s on/off; Bioruptor plus model UCD-300, Diagenode). Reduction and alkylation of disulphide bridges was performed by incubating the samples at 95°C for 5 min, followed the addition of iodoacetamide to a final concentration of 100 mM and incubation for 20 min at room temperature in the dark.

Samples were processed using S-Trap Mini Spin Columns (ProtiFi) according to the manufacturer's instructions. Briefly, samples were acidified by adding phosphoric acid to a final concentration of 1.2%, seven volumes of binding buffer (90% MeOH, 100 mM TEAB, pH = 7.1) was added to the samples, which were then transferred to the S-Traps, and spun at 4000g for 30 s. The trapped proteins were washed three times with the binding buffer. Protein digestion was performed by adding trypsin (Promega Biotech AB) 1:50 (enzyme:protein ratio) in 125 μl of 50 mM TEAB and incubating for 16 h at 37°C . Peptides were eluted with 0.2% of aqueous formic acid and 0.2% of formic acid in 50:50 water:acetonitrile. Following speed vacuum concentration peptides were dissolved in 0.1% TFA, quantified with the Pierce Quantitative colorimetric peptide assay (Thermo Fisher Scientific), and 1 μg was injected on the LC-MS/MS system.

Peptides were analysed in a Dionex Ultimate 3000 RSLCnano UPLC system in line-coupled to a Q-Exactive HF-X mass spectrometer (Thermo Fischer Scientific). Peptides were first trapped on an Acclaim PepMap100 C18 (3 μm , 100 \AA , 75 μm i.d. \times 2 cm, nanoViper) trap column and separated following a non-linear 120 min gradient on an EASY-spray RSLC C18 (2 μm , 100 \AA , 75 μm i.d. \times 25 cm) analytical column. The flow rate was 300 nl/min and the temperature was set to 45°C . A top 20 data-dependent acquisition (DDA) method was applied, where MS1 scans were acquired with a resolution of 120 000 (at 200 m/z) using a mass range of

(Continued)

375–1500 m/z, the target AGC value was set to 3×10^6 , and the maximum injection time was 100 ms. The 20 most intense peaks were fragmented with a normalized collision energy (NCE) of 28. MS2 scans were acquired at a resolution of 15 000, a target AGC value of 1×10^5 , and a maximum IT of 50 ms. The ion selection threshold was set to 8×10^3 and the dynamic exclusion was 40 s, while single charged ions were excluded from the analysis. The precursor isolation window was set to 1.2 Th. Each sample was analysed in triplicate.

Protein identification and relative label-free quantification was performed by means of the Proteome Discoverer v2.2 (Thermo Fisher Scientific) using SEQUEST HT as the search engine and a human protein database download from UniProt on 2019-01-15. For the search trypsin was selected as the protease, two missed cleavages were allowed, the tolerance was fixed at 10 ppm for MS1 and 0.02 Da for MS2, carbamidomethyl-cysteine was set as static modification while methionine oxidation, phosphorylation on serine, threonine and tyrosine, and protein N-terminal acetylation were selected as dynamic modifications. Peptides and corresponding proteins were identified with 1% of FDR.

Protein quantitative data were processed using Perseus v1.6.5.0. All quantitative values were log₂ transformed and standardized by subtracting the median in each sample. The technical replicates were averaged and only those proteins with quantitative values in at least four out of the seven samples, in at least one group were kept for further analysis. The resulting number was 7001 different proteins. Statistical tests, principal component and 2D functional annotation enrichment analyses were performed in Perseus. The R bioconductor package *limma* was used to fit a linear model and to compute moderated t-statistics.³⁴

Figures showing scatter plots with mean protein abundance between different cell types (induced neuron and fibroblasts) or conditions (HD- and Ctrl-iNs) show unpaired t-tests results. The code for these tests and visualization is available on GitHub (https://github.com/raquelgarza/iN_HD), as well as the visualization for the functional enrichment analysis (Fig. 2E), which was performed with STRING version 11.³⁵

DNA methylation array and analysis

Samples C1–C3, C5, C6, C9 and HD1–HD8 and HD10 were used for DNA methylation analysis. DNA was extracted from Ctrl- and HD-iNs converted in T25 flasks (200 000 fibroblasts cells plated for conversion per sample) using DNeasy Blood and Tissue Kit (Qiagen) following the manufacturer's instructions.

Bisulphite conversion was performed using the EZ DNA Methylation™ Kit from Zymo Research. Product No: D5004 with 250 ng of DNA per sample. The bisulphite converted DNA was eluted in 15 µl according to the manufacturer's protocol, evaporated to a volume of <4 µl, and used for methylation analysis using the Illumina Methylation EPIC array.

For analysis of methylation data, the statistical software R (version 4.0.3) was used. The 'minfi'³⁶ package (version 1.34) was used to determine the quality of methylation experiments and to derive

single probe scores per sample after normalization using the preprocessNoob() function.³⁷ All samples were deemed to have acceptable quality based on density plots of beta-values as well as signal intensities for control probes in the red and green channel. Sample age was derived from normalized beta values using the getAgeR function from the cgageR package (<https://github.com/metamaden/cgageR>).

Statistical analysis

In induced neuron conversion efficiency and purity analysis each dot represents either one control or a Huntington's disease adult human fibroblast cell line converted into induced neurons. Each cell line value is an average from several individual wells specified in each case in the figure legends. The well values are generated with high-content automated microscopy analyses. For 'target activation' analysis we scanned at least 100 fields (there are 189 fields in total). We excluded all wells having less than <50 valid fields. MAP2⁺ and TAU⁺ purity % was defined for each line by taking the average of:

$$\text{Purity} = \frac{\text{number of scanned MAP2}^+ \text{ or TAU}^+ \text{ cells}}{\text{number of DAPI}^+ \text{ cells}} \times 100 \quad (1)$$

Conversion efficiency % was defined by:

$$\text{Efficiency} = \frac{\text{number of MAP2}^+ \text{ or TAU}^+ \text{ cells}}{\text{number of plated cells}} \times 100 \quad (2)$$

Number of plated cells in a 24-well plate was 50 000 cells.

For all induced neuron morphology analysis each dot represents one control, or one Huntington's disease adult human fibroblast cell line converted into induced neurons. Each cell line value is an average from several individual wells specified in each case in the figure legend. The average value for one cell line was defined by: (average value of all wells/line) / (average value of all control wells performed with identical high-content automated microscopy settings and immunocytochemistry stainings). All neuronal profiling values (cell body area, neurite area, count, width, length and branchpoint count) are average relative values per cell.

In all qRT-PCR experiments five control and five Huntington's disease fibroblast and induced neuron cell lines were analysed using qRT-PCR by using three different reference genes. In experiments using 293T and iPSCs cell lines we used to test the silencing efficiency of g1HTT, g2HTT and g3HTT using qRT-PCR by using three different housekeeping genes.

In all autophagy measurements each dot represents one control or one Huntington's disease adult human cell line from the converted induced neurons. Relative dot number and area values were defined by: (average dot number or area of all wells/line) / (average dot number or area of all control wells performed with identical high-content automated microscopy settings and immunocytochemistry staining). Fold changes were defined for each line by first setting every individual non-treated cell line value to

Figure 2 Continued

1. Afterwards BAF, W, RAP, ST, g2HTT or g3HTT treated values were defined by:

$$\text{FC after treatment} = \frac{\text{average well value after treatment/line}}{\text{average non-treated well value}} \quad (3)$$

Correlation analysis were tested with Pearson's correlation coefficient. Correlation between the predicted age (based on Horvath clock) and real age of the donors was tested using Pearson's correlation coefficient. Two-tailed unpaired t-tests or paired t-tests were used to test differences between two groups. One-way ANOVA or non-parametric Kruskal-Wallis test was used depending on whether the data obeyed a normal distribution as defined by the D'Agostino-Pearson omnibus normality test to test differences between more than two groups. Two-way ANOVA corrected for multiple comparisons using Sidak statistical hypothesis testing was used when comparing values after various treatments. Multiplicity adjusted P-values were defined for each comparison. Data are presented as min/max box plots or mean and error bars which represent either standard error of the mean (SEM) or standard deviation of the mean (SD), specified in each figure legend.

Data availability

The mass spectrometry proteomics data have been deposited to the ProteomeXchange Consortium via the PRIDE³⁸ partner repository with the dataset identifier PXD024286.

The accession number for the RNA-seq and DNA methylation data reported in this paper is GEO: GSE182866.

Results

Direct induced neuron conversion of fibroblasts from Huntington's disease patients

We collected fibroblasts through skin biopsies from 10 individuals diagnosed with Huntington's disease and 10 age and sex-matched healthy controls (Ctrl) (Table 2). The Huntington's disease patients were all between 28–59 years of age with CAG repeats lengths in the range of 39–58 (Table 2). The CAG-repeat length was initially determined by genotyping patient biopsies and later confirmed in the established fibroblast cultures. Huntington's disease and control fibroblasts had a similar morphology and expanded at similar rates.

We reprogrammed the 20 fibroblast lines to induced neurons using our previously described protocol.^{21,25,39} In brief, this methodology includes a single lentiviral construct that expresses the transcription factors Achaete-scute homolog 1 (*Ascl1*) and POU Class 3 Homeobox 2 (*Pou3f2v* or *Brn2*) with two short hairpin RNAs (shRNA) targeting the RE1-silencing transcription factor (*REST1*)²¹ (Fig. 1A). Upon transduction, the fibroblasts rapidly developed a clear neuronal morphology with a reduction in the size of both the nuclei and cell body and the formation of long, elaborate neurites (Fig. 1B and Supplementary Fig. 1A and B). Over a time period of a few weeks, the reprogrammed fibroblasts transformed into mature induced neuron and started to express the neuronal markers MAP2 (neuron-specific cytoskeletal protein enriched in

dendrites) and TAU (a highly soluble microtubule-associated protein abundant in neurons) (Fig. 1B and Supplementary Fig. 1A and B). In addition to which they became electrically active as we have previously shown.²¹

We analysed the reprogramming capacity of fibroblasts derived from Huntington's disease patients in detail using a high-content automated microscopy analysis of the reprogrammed induced neurons. By quantifying the number and proportion of MAP2⁺ and TAU⁺ cells (as defined by DAPI) we found that the Huntington's disease fibroblasts converted into induced neurons 4 weeks post-transduction with a similar purity (number of induced neurons / number of DAPI cells) and conversion efficiency (number of induced neurons / number of starting fibroblasts) (Fig. 1C and Supplementary Fig. 1C and D) as to that seen with control fibroblasts. Neuronal purity and conversion efficiency were not affected by passage number (Supplementary Fig. 1E and F), and there was no difference in the rate of cell death between control and HD-iNs at 4 weeks, as determined by the number of induced neurons and DAPI⁺ cells at this stage (Supplementary Fig. 1G). Together, these data demonstrate that fibroblasts obtained from Huntington's disease patients can be reprogrammed to induced neurons with the same efficiency as that seen for healthy matched control individuals.

Transcriptome, proteome and epigenome profiling of induced neurons

To investigate molecular changes during the reprogramming process as well as molecular alterations in HD-iNs, we performed transcriptome and proteome analysis using RNA sequencing and shotgun proteomics on ctrl and HD-iNs, as well as the unconverted parental fibroblasts. To obtain a pure population of induced neurons for these analyses (in order to reduce background transcriptional noise), we established a procedure to FACS-purify induced neurons at 4 weeks post-conversion using neural cell adhesion molecule (NCAM+), a mature neuronal cell surface marker²⁵ (Fig. 1A).

We first analysed the RNA-seq transcriptome data across seven control and seven HD-iNs and fibroblasts and found that fibroblast and induced neuron samples (both control and Huntington's disease) were clearly distinguishable (Fig. 1D, Supplementary Fig. 2A and Supplementary Tables 4 and 5). We found high-level RNA expression of numerous genes that are known to be expressed in neurons in the induced neurons but not in the fibroblasts confirming successful neuronal conversion. Gene ontology analysis confirmed that the transcripts enriched in induced neurons represented cellular processes related to neuronal functions, such as synaptic signalling and regulation of membrane potential (Fig. 1E and Supplementary Table 6). On the other hand, transcripts enriched in fibroblasts were related to cell proliferation (Fig. 1F and Supplementary Table 7). We also investigated the presence of transcripts related to specific neuronal subtypes in the induced neurons and found genes related to several different neuronal subtypes, including both excitatory and inhibitory neurons (Fig. 1G), as well as an absence of neural progenitor markers both in the fibroblasts and in the induced neurons (Fig. 1G). This is in line with previous studies indicating that

Figure 3 Continued

number and size of LC3B, p62 and LAMP1 dots in the MAP2⁺ neurites of HD-iNs compared to controls (n = 6 lines). (I) Representative images of human post-mortem striatal tissue from a healthy control and three different Huntington's disease patients at different disease stages showing p62 accumulation specifically in the neurites as visualized by a neurofilament specific antibody. ***P < 0.001; **P < 0.01; *P < 0.05; two-tailed unpaired T-tests were used. All data are shown as mean ± SEM. Western blot values were normalized to Ctrl-iNs expression levels and corrected to actin values. Scale bar = 20 µm. See also Supplementary Fig. 4.

these types of induced neurons represent a mixed population of different types of maturing neurons.^{21–23,39}

Next, we analysed the shotgun proteomics data from the unconverted seven ctrl and seven Huntington's disease fibroblasts as well as the resulting induced neurons. The proteome analysis resulted in 4241 proteins being quantified and identified at high confidence in the majority of samples in at least one group (Fig. 1H and Supplementary Tables 8 and 9). When we compared the abundance of individual proteins, we found that the fibroblast samples and induced neurons (both control and Huntington's disease) displayed a high degree of proteomic difference when compared to each other (Supplementary Fig. 2B), similar to that which we saw in the transcriptomic analysis. In particular, proteins linked to neuronal function, such as synaptic vesicles proteins, were highly abundant in induced neurons, while proteins related to proliferation pathways, such as cell cycle and DNA replication were downregulated compared to fibroblasts (Fig. 1I and Supplementary Fig. 2C–E). Additionally, the metabolic profile seen in induced neurons, involved the upregulation of pathways like glycolysis, the lysosome and phagosome, demonstrating that these cells, to a large extent, mimic the metabolic state normally found in neurons (Fig. 1I and J and Supplementary Fig. 2F–H).

Several previous studies have demonstrated that induced neurons retain age-dependent molecular features.^{22,23,40–43} To confirm this in our induced neurons, we investigated if we could detect age-dependent epigenetic signatures in these cells. We used the Illumina Epic Methylation array to profile global DNA methylation patterns in six control and nine HD-iNs. A penalized regression model using a set of 353 CpGs defining the biological age by the Horvath epigenetic clock allows the prediction of the age of the donor.⁴⁴ We converted control and Huntington's disease donor cell lines into induced neurons and estimated the biological age of the resulting induced neurons. We found that in the Ctrl-iNs, the DNAm predicted biological age strongly correlated with the donor's actual real age (Pearson correlation coefficient $R^2 = 0.9639$, Fig. 1K). A previous study performed on post-mortem brain tissue indicated an increase in epigenetic ageing rates in patients with Huntington's disease.⁴⁵ In line with this, we also found significantly increased DNAm predicted biological age in the HD-iNs compared to the Ctrl-iNs ($P = 0.038$, Fig. 1K). Taken together, these data confirm that both control and HD-iNs retain epigenetic signatures consistent with aged neuronal cells and that induced neurons derived from patients with Huntington's disease have an increased biological age.

HD-iNs display alterations in proteins linked to autophagy

To identify molecular mechanisms potentially linked to Huntington's disease pathogenesis, we analysed HD-iNs for differences in their transcriptome and proteome when compared to Ctrl-iNs (Fig. 2A). Starting with the transcriptome, we found 516 mRNA transcripts that were upregulated in HD-iNs and 347 downregulated out of 14 104 detected transcripts compared to Ctrl-iNs, confirming previous findings that mHTT induces major transcriptional alterations (Fig. 2B and Supplementary Tables 10 and 11). However, gene ontology and network analysis only identified immunoglobulin production but not any other molecular or biological processes that were significantly enriched in the differentially expressed genes (Supplementary Tables 12 and 13). This suggests that while HD-iNs display transcriptome alterations, these alterations are not linked to distinct gene programs, making it difficult to link transcriptomic changes in HD-iNs to phenotypical alterations.

We next turned our attention to the differences between the proteomes of Ctrl-iNs and HD-iNs and found that 273 proteins were upregulated in HD-iNs while 137 proteins were downregulated out of 4951 proteins detected (Fig. 2C and Supplementary Tables 14 and 15). Noteworthy was the finding that the majority of proteins altered in HD-iNs were not changed at the RNA level. Out of the 410 proteins that were either up- or downregulated in HD-iNs only 21 of these genes were altered at the mRNA level (Fig. 2D and Supplementary Table 16). This suggests that only a very limited fraction of the differentially expressed transcripts that we detected resulted in significant changes at the protein level. Rather, the vast majority of changes at the protein level appear to be the result of post-transcriptional mechanisms.

Interestingly, when we performed gene ontology and network analysis of significantly dysregulated proteins in HD-iNs, we found that many of these proteins were functionally linked (Supplementary Tables 17 and 18). Downregulated proteins were enriched for cellular pathways such as the CAMKK-AMPK signalling cascade as well as autophagy related processes, while upregulated proteins were connected to ribosomal functions (Fig. 2E and Supplementary Tables 17 and 18). We also performed the same analysis in ctrl and Huntington's disease fibroblasts and found that ribosomal proteins were also upregulated in the Huntington's disease fibroblasts, in line with previous studies indicating that mHTT stalls ribosomes suggesting that translational alterations may be a ubiquitous downstream consequence of the presence of mHTT (Supplementary Tables 19 and 20).^{46,47} On the other hand, the proteins related to CAMKK-AMPK signalling and autophagy were only downregulated in HD-iNs and not in the corresponding Huntington's disease fibroblasts, indicating that these proteomic alterations are linked to neuron-specific cellular functions (Supplementary Fig. 3 and Supplementary Tables 18 and 20). We thus focused our further analyses on these neuron-specific proteome alterations.

In HD-iNs, several kinases in the CAMKK-AMPK pathway were downregulated, including CAMKK2, CAMK2G, AMPK and IRS1 as well as the autophagy regulator BECN1 (Fig. 2F). Moreover, suppressors of the AMPK pathway, PPP2R5E and PPP2R1B phosphatases were significantly upregulated in HD-iNs compared to healthy controls (Fig. 2F). Taken together, this omics-based analysis demonstrated that HD-iNs display an altered proteome with links to alterations in autophagy. Noteworthy, these alterations were cell-type specific, only present in the induced neurons but not in the fibroblasts and mainly due to post-transcriptional mechanisms that could not be detected by transcriptome analysis.

Subcellular alterations in autophagy in HD-iNs

One of the downregulated proteins detected in the proteomic analysis was BECN1, an autophagic regulator protein that plays a key role in autophagosome formation. Several studies support the importance of BECN1 in Huntington's disease pathology, as overexpression of it can slow the progression of Huntington's disease pathology in both cell and mouse models by inducing autophagy, while the expression of BECN1 in the brains of Huntington's disease patients declines with age.^{6,7,48,49} The downregulation of BECN1, as well as the other alterations in the CAMKK-AMPK signalling pathway, suggests that autophagy activity may be impaired in HD-iNs.

To investigate this in more detail, we first verified that in HD-iNs (but not the parental fibroblasts) there was a significant reduction of BECN1 levels using western blot analysis (Fig. 3A and Supplementary Fig. 4A). We then assessed autophagy activity in HD-iNs compared to Ctrl-iNs by measuring microtubule-associated

protein 1A/1B-light chain 3B (LC3B). LC3B conjugates from LC3B-I to LC3B-II during autophagosome formation. We found a reduction in the LC3B conjugation, as determined by assessing the ratio of LC3B-II over LC3B-I using western blot in HD-iNs (Fig. 3B), which was coupled to an increase in total LC3B-II levels, suggesting more autophagosomes in HD-iNs (Fig. 3B). We next measured p62 levels, which inversely reflects autophagolysosome degradation and found a non-significant trend for increased levels (Supplementary Fig. 4B). p62 is selectively degraded by autophagy and therefore, the level of p62 negatively correlates with autophagy.⁵⁰ We also measured the levels of LAMP1, which is present on endosomes and lysosomes including autophagolysosomes and autolysosomes but did not detect significant difference in HD-iNs (Supplementary Fig. 4B).⁵¹ In summary, there were alterations in basal autophagy in HD-iNs, primarily reflected by alterations in BECN1 and LC3B, in line with an increase in autophagosomes and most likely a reduction in autophagic flux.

In neurons, autophagosomes are formed in the neurites and then transported to the cell body where the active lysosomes are present.⁵² Moreover, degradative lysosomes in the soma can also be transported to target autophagosomes in the distal axons anterogradely in mature neurons.⁵³ To characterize autophagy alterations at a subcellular level, we performed immunocytochemistry analysis of LC3B, p62 and LAMP1 as well as an unbiased quantification of autophagosomes including the subcellular localization using high-content automated microscopy. This analysis revealed an increased number and size of LC3B puncta in HD-iNs, that was particularly apparent in the neurites of these cells (Fig. 3C and D). This demonstrates that autophagosomes accumulate specifically in neurites in HD-iNs. The increase in autophagosomes was coupled to an increased number and size of p62 puncta in neurites as well as an increase in the number and size of LAMP1-positive puncta at this same location (Fig. 3E–H), indicating that autophagosomes and autophagolysosomes remain in the neurites and fail to transport their cargo to the soma for degradation in HD-iNs.

Next, we investigated if the impairments are specific for autophagy-related vesicles or if vesicles not related to autophagy, such as endosomes were also affected. Previous studies have indicated that there is dysregulation in the early endosomal trafficking in different Huntington's disease cell lines.^{54,55} Moreover, Huntington's disease pathogenesis in some mouse models has been linked to decreased Rab11 activity in recycling endosomes.⁵⁶ We therefore analysed different endosomal proteins to discover whether there were any subcellular alterations in endosomal trafficking using high content automated microscopy. We found that while there was no difference in the cell body, a significant reduction in the number of early endosomal marker EEA1 dots were found in the neurites of HD-iNs compared to the Ctrl-iNs (Supplementary Fig. 4F and G). We found no significant difference between ctrl and HD-iNs when using RAB11, a marker for recycling endosomes (Supplementary Fig. 4H and I). These data indicate that while there are some alterations in early endosomal markers in the HD-iN neurites, these differences are not in line with the autophagy phenotype (increase of autophagolysosomes in neurites). Thus, these results suggest that the accumulation of vesicle-structures in the HD-iNs are specific to autophagy-related structures.

We next used immunohistochemistry to further verify the neurite-specific impairment of basal autophagy in Huntington's disease neurons using human post-mortem brain tissue (Table 1). We found no evidence of accumulation of p62 positive dots in the neurites of healthy controls identified by co-labelling with a Neurofilament specific antibody (Fig. 3I). In contrast, we found clear

p62 accumulation in the neurites in all Huntington's disease patients analysed regardless of disease stage (Fig. 3I). Taken as a whole, we therefore conclude that there is a subcellular, neurite specific autophagy alteration in Huntington's disease neurons.

Impaired autophagic flux in HD-iNs

We next focused on analysing autophagic flux in HD-iNs by modulating the autophagy pathway using pharmacological agents (Fig. 4A). First, we treated the cells using Bafilomycin A1 (Baf), a late-stage inhibitor of autophagy that blocks autophagosome-lysosome fusion and monitored autophagic activity by assessing the levels of LC3B-II and the LC3B-II/ LC3B-I ratio using western blot and immunocytochemistry. We found, in line with other studies an expected increase of LC3B-II expression both in the Ctrl- and HD-iNs but we failed to detect any changes in LC3B-II/LC3B-I ratio in the HD-iNs indicating an alteration in the autophagic flux detected by western blot (Supplementary Fig. 5). Using immunocytochemistry we found an increase in size of autophagosomes as visualized by LC3B-puncta, in the cell body of both Ctrl- and HD-iNs (Supplementary Fig. 5B–D). However, the number of LC3B dots increased significantly in the Ctrl-iNs, but not in the HD-iNs. Furthermore, there was an increase in p62-puncta count in both the cell body and neurites in HD-iNs but not in the Ctrl-iNs (Supplementary Fig. 5E–G). Thus, blocking autophagolysosomal formation in HD-iNs resulted in a further reduction in autophagy activity, suggesting that degradation of these structures occurs at a reduced rate in HD-iNs. In line with this observation, we found that the accumulation of autophagolysosomes in HD-iN neurites, as visualized by LAMP1-puncta, was completely abolished upon Baf-treatment (Fig. 4B–D). Thus, when the formation of new autophagolysosomes is prevented in HD-iNs, these cells are capable of dealing with the accumulation of these structures in the neurites. We further corroborated these results by treating the cells with Wortmannin (W), which blocks the initiation of autophagy by inhibiting phosphatidylinositol 3-kinase (PI3K) (Fig. 4A).⁵¹ This treatment resulted in a robust reduction of LAMP1-puncta in the neurites of HD-iNs with this treatment (Fig. 4B–D).

To further understand the autophagy impairment in HD-iNs we next used rapamycin (RAP) or torin, both of which activate autophagy at an early stage by inhibiting mTOR signalling (Fig. 4A). In Ctrl-iNs, RAP and torin treatment resulted in a clear reduction in LC3B-puncta in both the cell body and neurites, in line with the increased autophagic flux mediated by the treatment (Fig. 4E–G and Supplementary Fig. 6). However, in HD-iNs RAP treatment resulted in an increase in both the size and number of LC3B-puncta specifically in neurites (Fig. 4E–G). Torin treatment also failed to decrease the size and number of LC3B-puncta in the HD-iNs (Supplementary Fig. 6C–E). Thus, the impairment in autophagolysosome transfer and degradation that is present in HD-iNs prevents an increased autophagic flux in RAP or torin treated cells. Moreover, LAMP1 dot number and area was significantly reduced after RAP treatment in the Ctrl-iNs cell body where the active lysosomes are present and where the late autophagic structures are transported for degradation, while this was not seen in the HD-iNs. This further corroborates an autophagosomal transport failure in the HD-iNs. These results were verified by performing co-localization analysis for LC3B and LAMP1 (Fig. 4E, H and Supplementary Fig. 6A and B). While RAP clearly increased the autophagy flux in the cell body of Ctrl-iNs by an increased formation of LC3B-LAMP1 double positive late autophagy structures, we did not detect these structures in HD-iNs (Fig. 4E and H). On the contrary, HD-iNs exhibited a

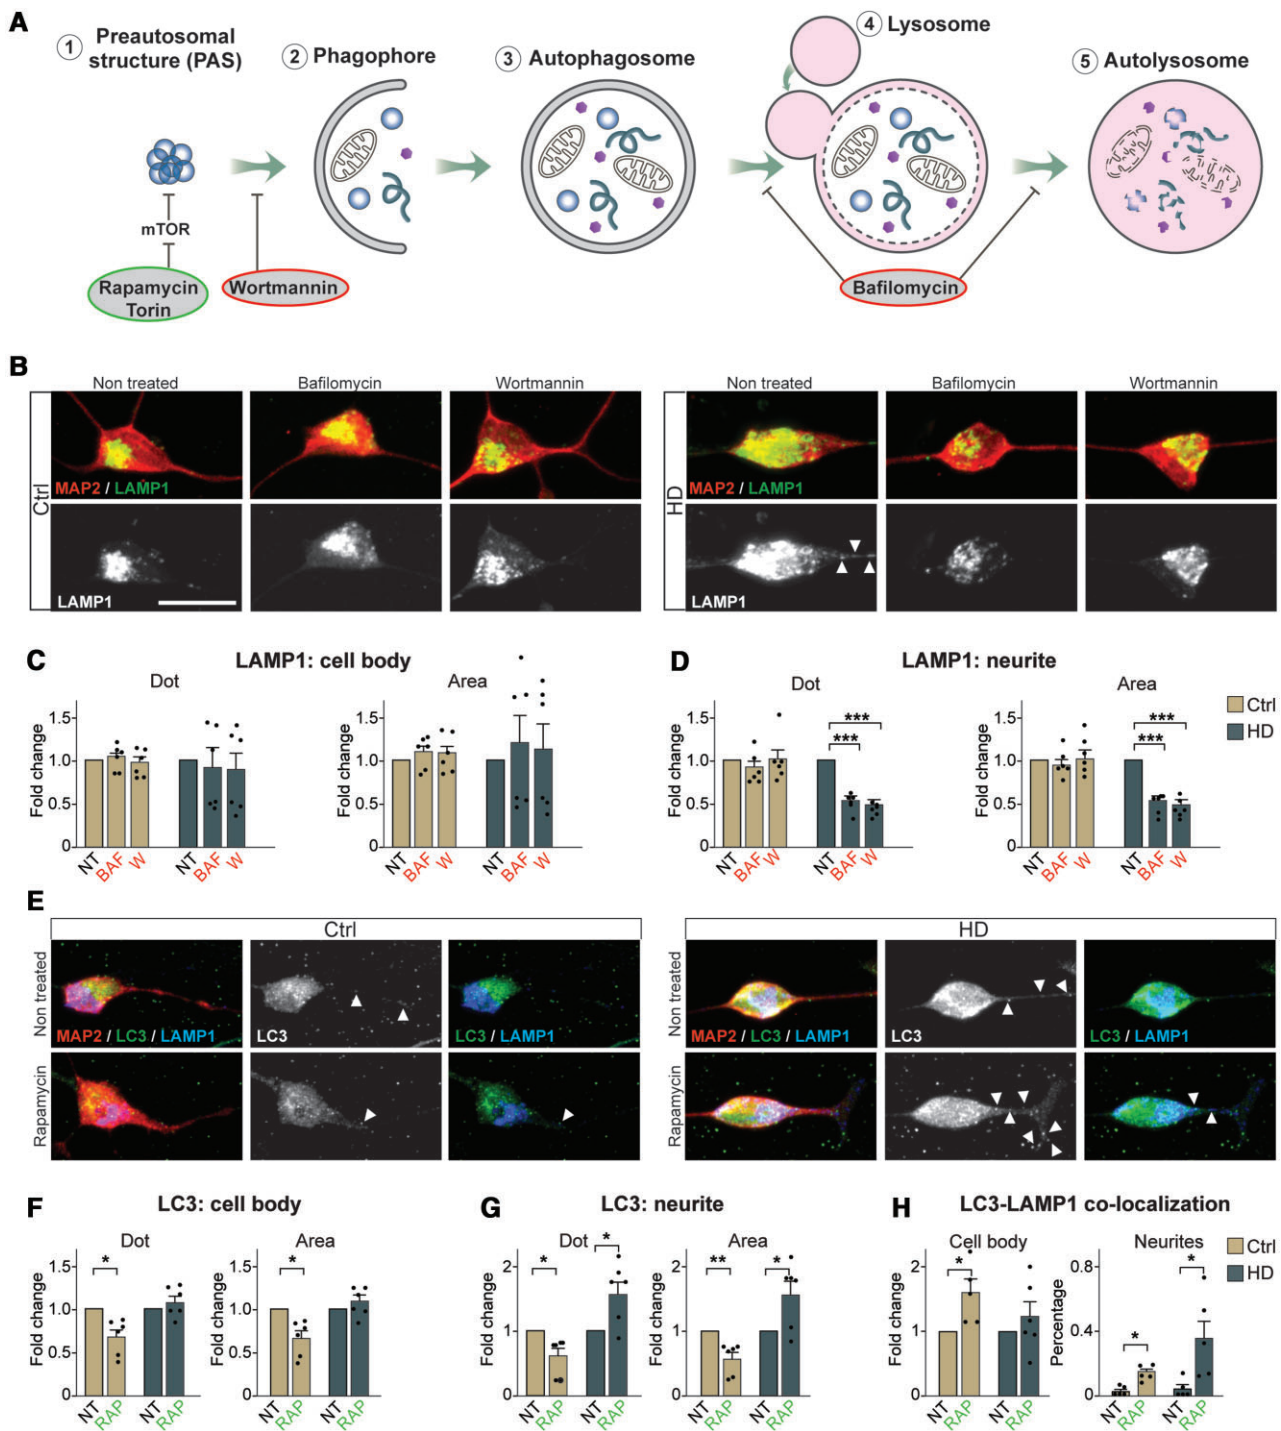

Figure 4 Autophagic flux is altered in the neurites in HD-iNs. (A) Schematic summary of the effect of different autophagy drugs. (B–D) Representative images and fold changes summarizing LAMP1⁺ dot number and area changes in the cell body and neurites of non-treated and Baf or W treated healthy control and HD-iNs ($n = 6$ lines). (E–G) Representative images of non-treated and rapamycin-treated healthy control and HD-iNs stained with the neuronal marker MAP2 together with LC3B and LAMP1. Arrowheads are indicating LC3B, p62, LAMP1 positive dots in the neurites. Statistical analysis shows a significant decrease after RAP treatment both in the number and size of LC3B dots in the MAP2⁺ cell bodies and neurites in the control induced neurons ($n = 6$ lines). Statistical analysis shows an opposing effect of RAP treatment regarding the amount and area of LC3B puncta in the neurites between control and HD-iNs. While in the control induced neurons rapamycin significantly decreased the number and size of LC3B positive dots in the MAP2⁺ neurites, HD-iNs exhibited the opposite, LC3B dots significantly increased both in number and size ($n = 6$ lines). (H) Statistical analysis showing a significant increase in LC3B-LAMP1 co-localization in the cell bodies of Ctrl-iNs, while there was no change in the HD-iNs ($n = 6$ lines). The percentage of LC3B-LAMP1 co-localization significantly increased both in the control and HD-iN neurites ($n = 6$ lines). *** $P < 0.001$; ** $P < 0.01$; * $P < 0.05$; two-tailed paired t-tests were used in almost all cases except H (neurites panel) where one-way ANOVA was used. All data are shown as mean \pm SEM. Fold changes are presented, except in H, neurite co-localization, where several data-points were 0 therefore the co-localization is presented as percentage between LC3B and LAMP1. Scale bar = 25 μ m. See also Supplementary Figs 5 and 6.

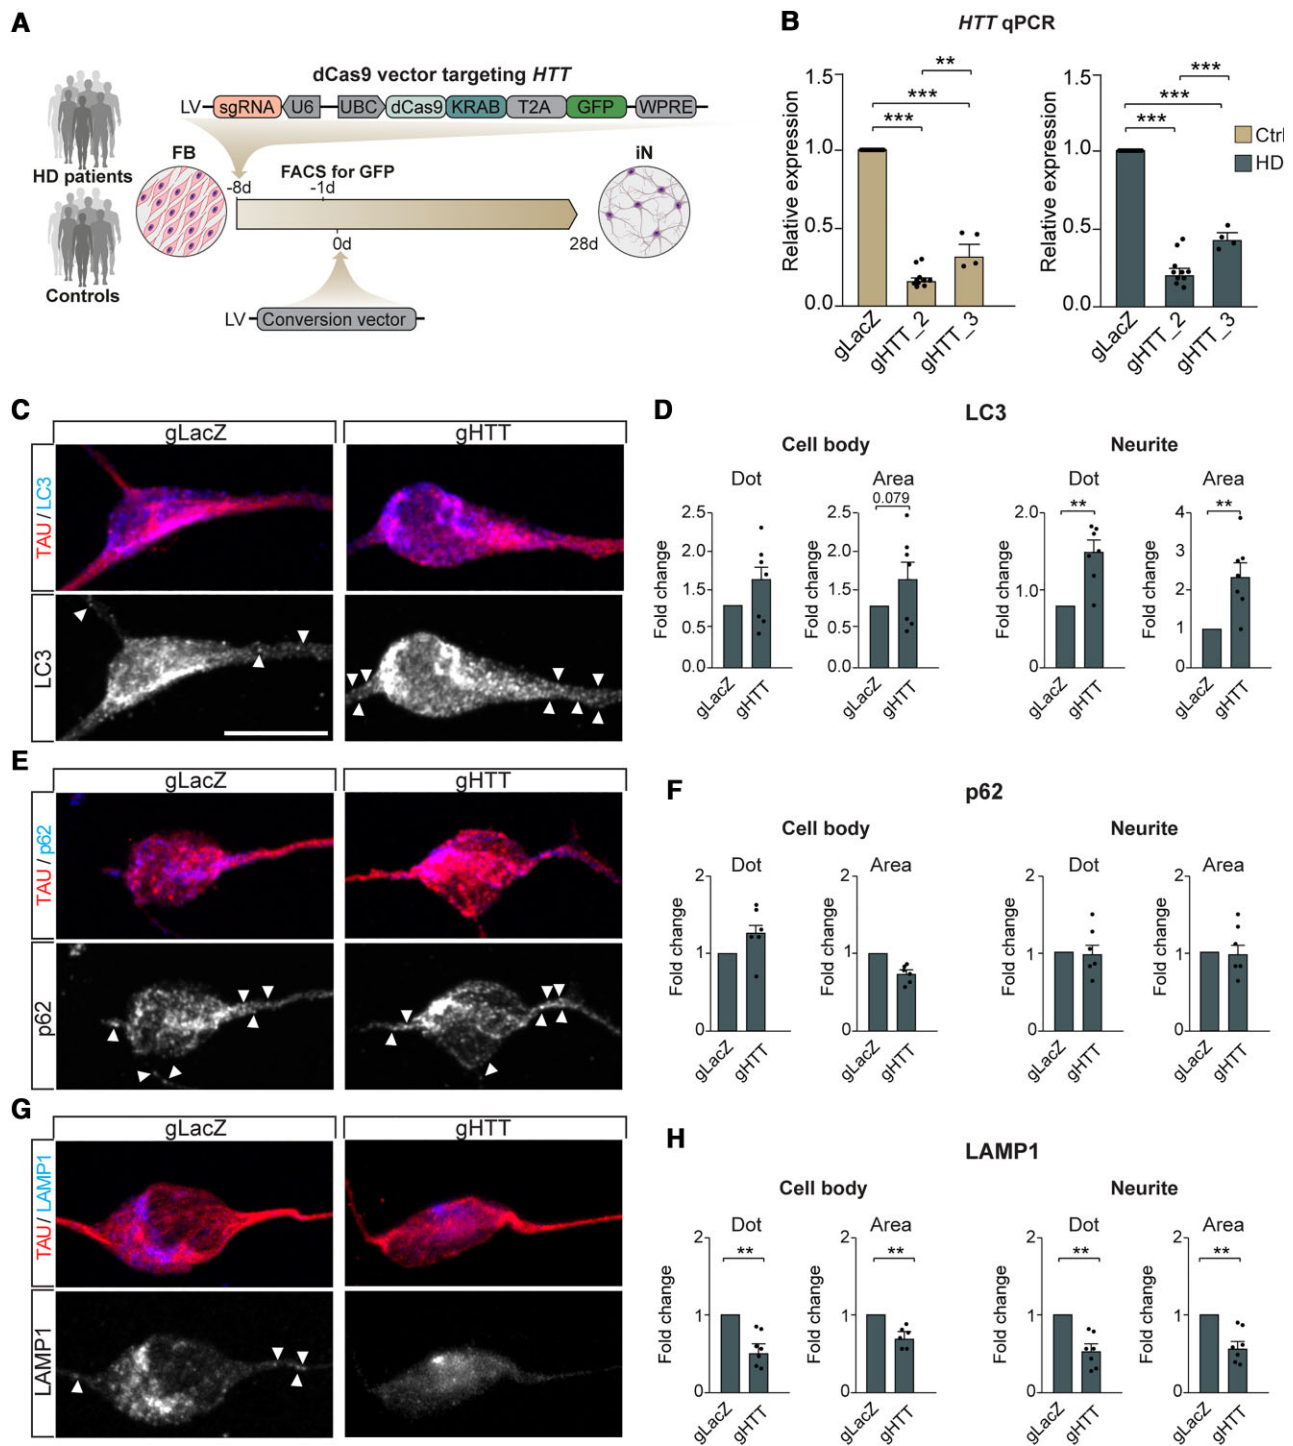

Figure 5 Silencing of HTT using CRISPRi further alters autophagy in HD-iNs. (A) Experimental overview. Fibroblasts from five Huntington’s disease patients and five healthy individuals were first transduced with lentiviral vectors targeting LacZ or HTT (sgRNA). After 7 days, GFP⁺ cells were FACS sorted and converted into induced neurons. (B) qRT-PCR revealed an efficient silencing of HTT using gRNA2 and gRNA3 both in control and HD-iNs ($n = 10$ replicates from five control and five HD-iN lines for LacZ and gRNA2 and $n = 4$ replicates from two control and two HD-iN lines for gRNA3). (C–H) Representative images and statistical analysis of LC3B, p62 and LAMP1 dot number and area in TAU⁺ cells in HD-iNs stably expressing LacZ and HTT gRNAs using CRISPRi ($n = 7$ replicates from five control and five HD-iN lines pooling gRNA2 and gRNA3 data). Arrowheads are indicating LC3B, p62, LAMP1 positive dots in the neurites. (** $P < 0.01$; * $P < 0.05$; two-tailed paired T-tests were used). All data are shown as mean \pm SEM. Fold changes are presented in all graphs. Scale bar = 25 μ m. FB = fibroblasts; iN = human induced neurons; DMEM = Dulbecco’s modified Eagle medium; Ndiff = Neural differentiation medium; sh = short hairpin; REST1/2 = RE1/2-silencing transcription factor; PGK = Phosphoglycerate kinase promoter; BRN2 = POU Class 3 Homeobox 2; ASCL1 = Achaete-Scute Family BHLH Transcription Factor 1; WPRE = Woodchuck Hepatitis Virus Posttranscriptional Regulatory Element; UbC = mammalian ubiquitinC promoter; KRAB = Krüppel associated box transcriptional repression domain; T2A = thosa asigna virus 2A self-cleaving peptides. significant increase only in neurite LC3B-LAMP1 co-localization after RAP treatment (Fig. 4E and H). This further verifies that while autophagolysosomes are formed in HD-iNs they fail to get degraded and transported to the cell body. Early activation of autophagy using RAP thus increases the amount of trapped autophagolysosomes in the neurites of HD-iNs.

Taken as a whole, these results demonstrate that HD-iNs show impairment in degrading autophagolysosomes. It appears that the cellular machinery is working at a reduced rate and cannot degrade the autophagy cargo, resulting in an accumulation in late stage autophagic structures. The reason for this impairment is likely to relate to the late autophagic structures getting stuck in the neurites and failing to be transported to the cell body where they should be degraded. This impairment in the last step of autophagy results in an overall reduction in autophagy activity. These observations are important from a therapeutic point of view as treatment paradigms to restore autophagy alterations in Huntington's disease should aim to enhance autophagolysosome transfer and degradation rather than activating autophagy at an early stage, which could actually worsen the pathology.

Cellular mechanisms underlying the autophagy impairments found in HD-iNs

We next investigated the molecular mechanisms underlying the autophagy impairment in HD-iNs. It has been suggested that protein aggregates are the key driver of the autophagy phenotype observed in neurodegenerative disorders. For example, long-term exposure to protein aggregates could eventually exhaust the autophagy machinery.^{57,58} On the contrary, HTT has also been suggested to be directly linked to the cellular signalling pathway that controls autophagic activity.^{59,60} HTT has been reported to directly bind to BECN1 via its polyQ-tract and modulation of this binding, either by loss of wtHTT levels or by the presence of an expanded polyQ-tract in mHTT, results in a reduction in BECN1 levels and an overall reduction in autophagic activity.^{7,49} wtHTT has also been reported to directly interact with p62 to facilitate cargo engulfment in autophagy, indicating that the loss-of-function of one wild-type allele of HTT in Huntington's disease may impair autophagy.⁶⁰

To investigate this further, we first looked for the presence of mHTT-aggregates in HD-iNs. In human brains, aggregated HTT protein can be quantified in samples extracted in lysis buffer. Through the use of western blot analysis with several different lysis conditions, we did not detect the presence of any mHTT-containing aggregates (Supplementary Fig. 7A and B) even though the expression of HTT-mRNA in fibroblasts and induced neurons was similar in both groups (Supplementary Fig. 7C). In addition, we performed formic acid extraction of the residual pellet as described

before²⁹ but failed to detect any specific bands, due to the low level of aggregated HTT in the HD-iN samples which caused only non-specific binding. Together, these experiments demonstrate that the autophagy impairments in HD-iNs are present without evidence for overt HTT aggregation.

We next investigated whether incomplete HTT-transcripts were generated in the fibroblasts or in the induced neurons since this has previously been reported in Huntington's disease cells and may be linked to cellular pathology.^{61,62} We first analysed our RNA-sequencing data, where we could not detect any retention of intron 1 in our Huntington's disease fibroblast and induced neuron samples (Supplementary Fig. 7E). To validate these results, we also used primers detecting exon 1–exon 2 and exon 1–intron 1 junctions using qRT-PCR. We could not detect any exon 1–intron 1 signal while we had a clear expression of exon 1–exon 2 both in the fibroblasts and in the induced neurons demonstrating that processing of the HTT transcript is not altered (Supplementary Fig. 7F). Thus, we found no retention of intron 1 in the Huntington's disease fibroblasts and in the HD-iN samples.

We next investigated the direct role of HTT in the regulation of autophagy in induced neurons. Previous studies showed that silencing HTT blocks retrograde transport of late autophagosomes, while depletion of the mHTT results in accumulation of late autophagic structures with undegraded cargo.^{9,10} Moreover, HTT is also involved in lysosomal transport.^{63,64} Since both wild-type and mutant HTT have been implicated in the regulation of autophagy we decided to investigate the consequence of transcriptional silencing of wtHTT/mHTT on the autophagy pathway in both Ctrl-iNs and HD-iNs.⁹ To this end we established a lentiviral-based CRISPRi approach to silence HTT-expression (Fig. 5A). The CRISPRi-vector expressed a dead Cas9-KRAB fusion protein that was linked to a GFP reporter as well as a guide RNA (gRNA) targeted to the area around the HTT transcription start site (Fig. 5A). This vector design allows for the binding of dCas9-KRAB to the HTT loci, thereby resulting in the establishment of local heterochromatin and subsequent transcriptional silencing. We optimized the vector construct by testing different gRNAs and MOIs in HEK293T cells and human iPSCs and ultimately found two different gRNAs, targeted to a region just downstream of the HTT transcription start site, that very efficiently silenced both alleles of HTT (Supplementary Fig. 8A).

We transduced control and Huntington's disease fibroblasts with the CRISPRi-*HTT* vector and FACS purified GFP expressing cells (Fig. 5A). This resulted in efficient silencing of both alleles of *HTT* in the patient-derived fibroblasts as quantified with qRT-PCR (Supplementary Fig. 8B). We then proceeded to generate induced neurons from the CRISPRi-*HTT* silenced fibroblasts (Fig. 5A). After 4 weeks of conversion, we confirmed that *HTT* remained silenced

Figure 6 Continued

showing control and HD-iNs expressing mature neuronal markers like MAP2 and TAU. (C) The average relative cell body area and number of branch-points per cells as defined by MAP2 staining using high-content automated microscopy analysis shows no difference between control and HD-iNs. Relative neurite area, length and width per cell was significantly reduced in the HD-iNs compared to the healthy controls ($n=9$ lines for controls, 96 wells analysed in total; $n=10$ lines for HD, 119 wells analysed in total). (D) Biological processes connected to microtubules and cytoskeletal organization selected from the gene ontology functional enrichment analysis (STRING, biological process) of proteins downregulated in HD-iNs compared to Ctrl-iNs. Bar plots represent fold enrichment. Circles represent *P*-values ($n=7$ control and $n=7$ Huntington's disease fibroblast and induced neuron lines; $P<0.05$). (E) Tubulin proteins significantly dysregulated between control and HD-iNs ($n=7$ control and $n=7$ HD-iN lines). (F) Neurite area and length per cell is reduced after autophagy impairment in control iNs, while it is not further reduced in HD-iNs ($n=3$ control and $n=3$ HD-iN lines, 9–9 wells analysed in each condition). (G) Neurite area and length per cell is reduced after starvation in HD-iNs, while it is not changed in control iNs ($n=6$ for Ctrl-iN lines and $n=5$ for HD-iN lines, 12 wells analysed in total for Ctrl-iNs and 10 for HD-iNs). (H) Relative neurite area and length per cells were not changed in the *HTT* (wild-type and mutant) silenced HD-iNs compared to the LacZ transduced. *HTT* silencing did not affect neurite area and length in the control induced neurons ($n=5$ control and $n=5$ HD-iN lines for LacZ and gRNA2, $n=2$ control and $n=2$ HD-iN lines for gRNA3). *** $P<0.001$; ** $P<0.01$; * $P<0.05$; two-tailed unpaired *T*-tests were used in C, E and G. Ordinary one-way ANOVA was used in F. Two-way ANOVA was used in H. All data are shown as mean \pm SEM in C and F–H. All data are shown as min/max box plots in E. Scale bar = 50 μ m. See also Supplementary Fig. 10.

in the induced neurons after conversion and that CRISPRi-*HTT* treatment did not impact on reprogramming efficacy (Fig. 5B and Supplementary Fig. 8C–F). The resulting *HTT*-silenced HD-iNs and Ctrl-iNs were then analysed using immunocytochemistry for LC3B, p62 and LAMP1 spots in the cell body and in the neurites.

We focused first on silencing of *HTT* in the Ctrl-iNs. Previous studies have demonstrated that wild-type *HTT* has an essential function in autophagy, as it contains an autophagy-inducing domain and it also facilitates axonal trafficking of autophagosomes.^{9,10} Moreover, *HTT* functions as a scaffold in autophagy where it physically interacts with p62 and depletion of *HTT* reduces the association of p62 with LC3B and other substrates of autophagy.⁶⁰ When silencing *HTT* in Ctrl-iNs, we found that while LC3B dot number count or area were not affected, the number of p62 positive puncta significantly increased in the neurites of Ctrl-iNs, confirming its role in regulating autophagy or other mechanisms related to p62 degradation (Supplementary Fig. 9A and B). Notably, the number and area of LAMP1 puncta significantly decreased but only in the neurites of *HTT* silenced Ctrl-iNs (Supplementary Fig. 9C). Thus, silencing of *HTT* in the Ctrl-iNs resulted in the alteration of autophagic activity characterised by increased p62 accumulation and reduction in the endolysosomal marker LAMP1. These findings are in line with previous studies demonstrating that *HTT* facilitates cargo recognition by modulating the assembly of the cargo receptors and autophagy proteins. Moreover, these findings highlight that silencing *HTT* in the Ctrl-iNs results in a different autophagy impairment to that seen in HD-iNs.

Next, we focused on the effect of silencing *HTT* in HD-iNs on autophagy. As described above it is important to highlight that CRISPRi experiments resulted in a highly efficient silencing of both healthy and m*HTT* alleles in the HD-iNs (Fig. 5B). Moreover, as described above, HD-iNs display a neurite specific late-stage autophagy alteration with increased LC3B, p62, LAMP1 dot number and area. When silencing *HTT* (both the wt*HTT* and m*HTT* allele) in HD-iNs we found a further accumulation of LC3B both in terms of the number and their size in the neurites, while p62 expression was not significantly affected (Fig. 5C–F). LAMP1 was significantly reduced in the HD-iNs after silencing *HTT* both in the neurites and in the cell body (Fig. 5G and H). These results suggest that some of the autophagy impairments are restored by silencing m*HTT*, most notably there is a significant reduction of LAMP1 in the neurites. However, with this silencing comes another type of autophagic impairment likely due to a loss-of-function of the wild-type *HTT* (Fig. 5C–H and Supplementary Fig. 9). Thus, CRISPRi silencing of wt*HTT*/m*HTT* does not substantially rescue the autophagy impairment in HD-iNs, most likely due to the important role of wt*HTT* in the control of autophagy.

The autophagy impairment in HD-iNs results in reduction in neurite complexity

We finally explored the cellular consequences of the impaired autophagy in HD-iNs. It is well established that Huntington's disease neurons tend to display alterations in neurite arborization and complexity, and these impairments are thought to contribute to the early disease process and possibly clinical expression.^{40,65–67} Importantly, autophagy has been directly linked to neurite formation, since inhibition of this degradation pathway reduces neurite growth and branching complexity.^{52,68} To investigate whether HD-iNs have an altered neurite morphology and if this is linked to the autophagy impairments found in the cells, we performed a detailed analysis of neural morphology of the reprogrammed cells

using high-content automated microscopy (Fig. 6A and Supplementary Fig. 10A and B). After 4 weeks of conversion, we found a significant decrease in neurite complexity in HD-iNs as measured by total neurite area, the number of neurites per cell, neurite length and neurite width (Fig. 6B, C and Supplementary Fig. 10C–F). This phenotype was not a consequence of a slower maturation of HD-iNs, since we observed a similar reduction in neurite number, length and complexity even when we extended the conversion period to 7 weeks (Supplementary Fig. 10G–M). Also, at this extended conversion period we found no difference in cell number, cell body size, conversion efficiency or purity when comparing HD-iNs and Ctrl-iNs. (Fig. 6C and Supplementary Fig. 10M–O).

At a molecular level we found that many proteins that were downregulated in HD-iNs were connected to the microtubule system, which plays a fundamental role in the maintenance of axonal homeostasis by preserving axonal morphology and providing tracks for protein and organelle transport. A significant reduction was seen in proteins belonging to the tubulin protein superfamily, such as TUBGCP2, TUBA1C, TUBAL3, which are all involved in neuronal microtubule migration, axonal assembly and neurodegeneration (Fig. 6D and E). Notably, these alterations in the microtubule system were dysregulated at a post-transcriptional level as the tubulin superfamily protein members were not different at the RNA level (Supplementary Fig. 10P).

Autophagosomes form at the axon terminal and fuse with lysosomes during a dynein-mediated transport to the soma. Moreover, lysosome transport is also mediated via microtubules in the neurites.⁶⁹ To investigate a direct link between the reduced neurite morphology in HD-iNs and autophagy, we analysed neuronal morphology after inhibition or activation of autophagy using Baf or W and starvation, respectively. We found a significant reduction in the Ctrl-iNs neurite area and length when inhibiting autophagy using Baf or W. In contrast, HD-iNs did not exhibit any further reduction in neurite area or length after autophagy suppression (Fig. 6F). These data suggest that while Ctrl-iNs neurite morphology is affected by autophagy impairment using different pharmacological agents, HD-iNs do not show any further morphological changes, likely due to an already existing autophagolysosomal transport failure.

Next, we used amino acid free starvation to activate autophagy in the induced neurons. In response to starvation, cells recover nutrients through autophagy by increased AMPK activation and increased mTOR inhibition. This short-term autophagy activation through starvation did not have any major effect on the neuronal morphology of the Ctrl-iNs since neurite area and length were not affected (Fig. 6G). On the other hand, the neuronal morphology of HD-iNs was significantly affected, neurite area and length significantly decreased after starvation (Fig. 6G), suggesting that HD-iNs could not cope even with this short-term starvation activation of autophagy. Lastly, we analysed the effect of CRISPRi editing on the neurite morphology after silencing of *HTT* expression in Ctrl-iNs and HD-iNs. CRISPRi silencing did not rescue the reduced neurite area nor neurite length in the HD-iNs (Fig. 6H). HD-iNs were significantly shorter and smaller even after silencing both *HTT* alleles in the HD-iNs compared to the Ctrl-iNs (Fig. 6H). Together, these results suggest that the abnormal neuronal morphology present in the HD-iNs is directly linked to impairments in autophagy.

Discussion

The pathogenic processes underlying Huntington's disease have been difficult to elucidate, in part due to the fact that age-dependent human neurodegenerative disorders are challenging

to study. Post-mortem material is limited, both in terms of availability and experimental possibilities and provides only a static snapshot of the consequence of disease. Several mouse models have been developed to study Huntington's disease, including both transgenic overexpression mice as well as those based on knock-in technology. While these models vary in regards to both the severity and progression of the pathology they are limited in their recapitulation of the human disease, in part due to the shorter lifespan of rodents compared to human.^{70–73} This has led to the use of transgenic mHTT-alleles with very long CAG repeats (sometimes >100 CAGs), where the pathology is accelerated and thus possible to study in mice. However, this many repeats are rarely, if ever, seen in routine clinical practice looking at adult patients with Huntington's disease. In cases where they are seen, they are associated with the rare juvenile form of the disease, in which the disease process may be significantly different from Huntington's disease associated with more typical CAG repeat lengths.⁷⁴ While alternative models have been generated, including for example transgenic mHTT rats with shorter CAG repeats and pathology, there are still many challenges to modelling Huntington's disease in a non-human system.⁷⁵ These issues have contributed in part to the lack of effective treatments and it is therefore critical to establish model systems that recapitulate the human disease progression, including age-dependent processes.

Recent advances in cellular reprogramming have allowed for the establishment of iPSCs that can be efficiently differentiated into neurons, making it possible to obtain human patient-derived Huntington's disease neurons^{76–79} with the potential to generate isogenic control lines. While iPSC-derived neurons have become an essential tool for studying neuronal function, there are limitations when studying the underlying molecular mechanisms of late-onset neurodegenerative disorders.^{80,81} A drawback with iPSCs is that during the reprogramming process epigenetic marks associated with ageing are erased, thereby transforming them to a juvenile state.⁸² Thus, the study of iPSC-derived neurons is limited to young cells, which is suboptimal since age is a key determinant of Huntington's disease pathology.^{2,3} As a consequence, most HD-iPSCs studies with well documented phenotypes are of limited utility.^{76–79} As an alternative to iPSCs, we and others have recently developed direct lineage reprogramming.^{39,81} By overexpressing and knocking-down key transcription factors it is possible to reprogram human fibroblasts directly into neurons, without going through a juvenile state. This approach allows for the generation of patient-derived neurons that retain age-associated epigenetic marks.^{21–23}

In this study we have used direct reprogramming of patient-derived fibroblasts to induced neurons to study disease mechanisms in Huntington's disease. The key advantage of this approach is the possibility to study patient-derived neurons with an ageing phenotype—two very important characteristics which combined are unique for this model system. With this system we were able to detect clear disease-related phenotypes when studying induced neurons from Huntington's disease individuals with CAG repeats in the pathological range normally seen in clinic in patients.⁴ The DNA-methylation analysis confirms that the induced neurons we generated retained age-dependent epigenetics marks and indeed that there are even Huntington's disease specific epigenetic alterations in line with an enhanced biological age of Huntington's disease patients, as previously has been suggested.⁴⁵ The transcriptional changes that occur upon ageing as a consequence of epigenetic alterations are likely to contribute to pathology in Huntington's disease and importantly appears to be recapitulated by our induced neuron

model system. However, there are also limitations to induced neurons. Fibroblasts carry skin-specific, age-related changes that are not relevant for Huntington's disease pathology and in addition relevant brain-specific epigenetic changes may not be captured. Also, while induced neuron cells display many characteristics of neuronal-like cells they do not develop into the mature subtype-specific neurons that can be generated from iPSCs, a drawback that may limit their utility for the study of different neuronal phenotypes. Finally, the generation of isogenic controls remains extremely challenging when working with fibroblasts as compared to iPSCs and the selection and size of the cohort therefore becomes very important when working with induced neurons—namely to offset this problem it is possible to study many different induced neuron cell lines in contrast to what can be done with iPSC derived neurons. Our current cohort therefore used 10 Huntington's disease individuals and for the majority of experiments we only included the seven individuals with CAG repeats in the shorter pathological range. It is promising that even with this relatively small cohort, we were able to identify and study disease mechanisms linked to autophagy alterations. This indicates that in future studies, the use of carefully selected cohorts should be able to start addressing how age, life-style, sex and CAG-repeat length influence the molecular biology of Huntington's disease neurons since the model system allows for easy molecular analysis including several omics-approaches (as we have shown in this paper).

Our transcriptome data clearly demonstrate that fibroblasts undergo a major transcriptional change when converted to induced neurons, primarily characterized by the activation of neuronal gene programmes. This is linked to a similar change in the proteome, including a transition of the metabolic state to that of neurons. Notably, we also detected almost a thousand transcripts that were differentially expressed when comparing induced neurons from healthy controls to mHTT carriers, confirming many previous reports of transcriptional dysregulation in Huntington's disease.^{6,7,83} However, many of these transcriptional changes could not be detected at the protein level in our proteomics dataset. In fact, most alterations in genes related to autophagy were not changed at the transcriptional level and are likely to be a consequence of post-transcriptional mechanisms. Some of this discrepancy could be due to technical challenges when comparing datasets obtained from RNA-sequencing and mass-spectrometry, which are very different in terms of sensitivity, quantification and normalization making a direct comparison challenging. Still, our data indicate that proteomic analyses are an important addition when studying molecular alterations in Huntington's disease and other neurodegenerative disorders where post-transcriptional mechanisms are likely to be disrupted.

Several studies have demonstrated that the presence of mHTT interrupts autophagy, contributing to the impaired clearance of aggregated proteins.^{6–10,55} In various models of Huntington's disease, different kinds of impairments in autophagy have been described including an increased number of autophagosomes (which sometimes appear empty), disrupted vesicle trafficking and impaired autophagosome-lysosome fusion and dynamics.^{7,8,10,84} It is also not clear if impaired autophagy directly contributes to the build-up of protein aggregates or if the aggregates themselves influence the activity of autophagy.^{7–10,60,85–89} It has been speculated that defects in the autophagic machinery can lead to a negative feedback loop, whereby mHTT aggregation leads to a further dysregulation of autophagy causing increased mHTT accumulation and neurotoxicity.^{7,89–91} Thus, while there are numerous experimental reports on autophagy impairments in Huntington's disease, it remains

unclear which of these are specific to the model system and which are relevant to the actual disease.^{7–10,60,85–89} This is important given its therapeutic implications and the fact that trials are now starting to appear in the clinic looking at autophagy enhancing agents. In HD-iNs, we found a subcellular, neurite specific autophagy impairment, with an accumulation of LAMP1-positive late autophagic structures. We also show that this is a consequence of an impaired transport of these structures to the cell soma where they should be degraded. This finding provides an answer as to why neurons are particularly vulnerable in Huntington's disease and represent a novel therapeutic target—restoration of autophagolysosome transfer to the cell soma.

The underlying molecular mechanism for the autophagy impairment in HD-iNs appears to be linked to the AMPK pathway, since several factors in this pathway were dysregulated. AMPK is a key energy sensor that promotes catabolic pathways while shutting down ATP consuming processes required for cell growth.^{92–94} AMPK inhibits cell growth by inhibiting mTORC signalling and protein synthesis downstream of mTORC1. Energy impairments such as decreased mitochondrial biogenesis and trafficking, oxidative stress, increased apoptosis, and ATP deficit all have been implicated in Huntington's disease pathogenesis.⁶⁹ Neurons are energetically demanding cells and thus highly vulnerable to abnormalities in cellular respiration. Our findings point towards boosting autophagy by specifically targeting the AMPK pathway. In line with this, we and others have also shown that BECN1 overexpression can rescue some aspects of Huntington's disease pathology in various models.^{6,7,48,49} Moreover, genetic and pharmacological activation of AMPK has been shown to protect dysfunctional and vulnerable neurons in Huntington's disease in nematode, cellular and mouse models.^{95,96} An impairment of autophagy in neurons will have multiple pathological consequences.^{13,14} Autophagy is implicated in neurogenesis, synaptogenesis, the control of post-transcriptional networks and protein aggregation.^{6,97–99} Thus, impairment of autophagy could underlie many of the early cellular disease phenotypes observed in Huntington's disease.^{100,101} As such, the development of specific autophagy-boosting therapies is promising as they have the potential to directly restore other dysfunctional intracellular processes.

Since HD-iNs retain ageing epigenetics characteristics, our results indicate that autophagy impairments in Huntington's disease may be due to a combination of age-related epigenetic alterations and mHTT-mediated post transcriptional processes. Exactly how the presence of a mHTT-allele results in a reduction in the transport of autophagolysosomes from neurites remains unknown, but a combination of an age-related alteration in autophagy-control together with a direct mHTT-mediated protein–protein interaction appears the most likely scenario. For example, mHTT has previously been found to directly interact and destabilize BECN1, which is in line with the reduction of BECN1 protein that we found in HD-iNs.^{5,7,48,49,55,102} How ageing and the epigenetic alterations influences the disease pathology and autophagy impairments is currently unknown but will be interesting to investigate in order to find mechanistic links between these phenomena.

Our study also has direct implications for the development of therapies working on mHTT-silencing. Such therapies are considered a very promising possibility to successfully treat Huntington's disease patients and clinical trials are already underway.^{17,103,104} Our results suggest that the development of allele-specific silencing of mHTT may be key to the success of such therapies given that wtHTT is directly involved in the control of cellular pathways controlling protein degradation. This could

explain some of the findings for example in the recently halted ASO trial in Huntington's disease.^{105,106} Thus, while the silencing of mHTT will certainly have beneficial consequences, as demonstrated in our study by efficiently lowering LAMP1 in the neurites, the silencing of wtHTT will also come with loss-of-function consequences on similar cellular pathways.

In summary, we have developed a novel cell-based model of Huntington's disease that allows for the study of aged patient-derived neurons. We found that HD-iNs display distinct autophagy alterations, characterized by a blockage in autophagolysosome transfer and degradation. Our results thus identify a novel therapeutic target through autophagy while also helps to advocate for the development of allele specific silencing-based Huntington's disease therapies.

Acknowledgements

We are grateful to all members of the Jakobsson lab and Elena Cattaneo for stimulating discussions and useful comments on the manuscript. We also thank U. Jarl, J. Johansson, M. Persson Vejgård and E. Ling for technical assistance. We also thank Dr Anna Hammarberg for her valuable help with high-content automated microscopy and FACS experiments.

Methylation profiling was performed by the SNP&SEQ Technology Platform in Uppsala (www.genotyping.se). The facility is part of the National Genomics Infrastructure supported by the Swedish Research Council for Infrastructures and Science for Life Laboratory, Sweden.

Funding

This research was supported by the NIHR Cambridge Biomedical Research Centre (BRC-1215-20014). The views expressed are those of the author(s) and not necessarily those of the NIHR or the Department of Health and Social Care. This research was funded in whole, or in part, by the Wellcome Trust 203151/Z/16/Z. For the purpose of Open Access, the author has applied a CC BY public copyright licence to any Author Accepted Manuscript version arising from this submission. RAB was a NIHR Senior Investigator.

The work was supported by grants from the Swedish Research Council (# K2014-62X-22527-01-3 and # K2014-62X-20404-08-5 and # 2020-02247_3), the Swedish Foundation for Strategic Research (# FFL12-0074), the Swedish Brain Foundation (# FO2014-0106); the Swedish excellence project Basal Ganglia Disorders Linnaeus Consortium (Bagadilico), the Swedish Government Initiative for Strategic Research Areas (MultiPark & StemTherapy), the Stiftelsen Olle Engkvist Byggmästare (# 186-655), the Petrus and Augusta Hedlunds Foundation (# M-2020-1272), Jeanssons Foundation (# F 2020/1735), the Thelma Zoéga Fund for Medical Research (# TZ 2017-0057 and # TZ 2018-0052), the Lars Hierta Memorial Foundation (# FO2017-0108 and # FO2018-0058), the Greta and Johan Kocks Foundation (# F 2017/1852), the Tore Nilsons Foundation For Medical Research (# 2018-00558 and # 2017-00505 and # 2016-00296 and # 2020-00824), the Åhlen Foundation (# mA7/h15), the Crafoord Foundation (# 20170592 and # 20190801 and # 20200621), the Åke Wibergs Foundation (# M18-0044), the Thorsten and Elsa Segerfalk Foundation (# F 2017/813 and # F 2019/991), the Anna-Lisa Rosenberg Fund for Neurological Research (# F 2017/1890), the Neuro Foundation (# F2021/102), the Sigurd and Elsa Goljes Minne Foundation
