36 **ABSTRACT**

37

38 Approximate Entropy (ApEn) is frequently used to identify changes in the complexity of
39 isometric force records with ageing and disease. Different signal acquisition and
40 processing parameters have been used, making comparison or confirmation of results
41 difficult. This study determined the effect of sampling and parameter choices by
42 examining changes in ApEn values across a range of submaximal isometric
43 contractions of the First Dorsal Interosseus. Reducing the sample rate by decimation
44 changed both the value and pattern of ApEn values dramatically. The pattern of ApEn
45 values across the range of effort levels was not sensitive to the filter cut-off frequency,
46 or the criterion used to extract the section of data for analysis. The complexity
47 increased with increasing effort levels using a fixed ' r ' value (which accounts for
48 measurement noise) but decreased with increasing effort level when ' r ' was set to 0.1
49 of the standard deviation of force. It is recommended isometric force records are
50 sampled at frequencies >200 Hz, template length (' m ') is set to 2, and ' r ' set to
51 measurement system noise or 0.1 SD depending on physiological process to be
52 distinguished. It is demonstrated that changes in ApEn across effort levels are related
53 to changes in force gradation strategy.

A healthy physiological output signal results from the integration of many processes, and allows for a full range of responses to any physiological demands [1]. As the physiological systems underlying these processes degenerate as a result of ageing or pathology, the possible values of the physiological output become restricted, which results in a decreased complexity [2, 3]. The measurement of changes in complexity are therefore useful in identifying early and pre-clinical degeneration, and, conversely, successful rehabilitation and preventative strategies [3]. Here complexity refers to a signal which has detailed structure. Approximate Entropy (ApEn) is a statistic that quantifies the complexity and regularity of physiological time series [4]. For example, a sine wave is regular and therefore has an ApEn value close to 0; while white noise consists of random independent samples and has an ApEn value close to 2.

The ApEn statistic derives from the Kolmogorov-Sinai entropy in an information theory sense, but, whereas the latter requires large amounts of data to achieve convergence and is not robust to noise, the former has the advantage for physiological signals that it can account for noise, is robust to outliers, and is applicable to relatively short data lengths [5]. ApEn is designed for use as a comparative measure such that for a defined template “length”, ‘ m ’, and noise amplitude, ‘ r ’, a more regular (less complex) data series of length N points has a lower $ApEn(m,r,N)$ value (i.e. closer to zero) than a more irregular data series of the same length [6].

80 ApEn has also been used to quantify complexity in human motor behaviour, and in
81 particular in isometric force records from voluntary muscle contractions [7, 8]. As the
82 force fluctuations are influenced by changes in motor unit activity [9] quantifying the
83 ApEn of an isometric force record provides insight into motor control strategies and
84 how they may change with ageing, disease, and training interventions [10]. For the
85 comparison of older with younger adults, the differences in ApEn are consistent with
86 the age-related loss of complexity hypothesis, though these changes may be a
87 characteristic of isometric tasks only [7, 11]. ApEn has also been used to construct an
88 entropy based theory of adaptation to different motor task requirements under different
89 conditions of environmental information [8]. The use of ApEn therefore forms the basis
90 for a number of hypotheses and explanations in relation to the production of isometric
91 force, and theories of motor behaviour, control, and ageing.

92

93 Given the scope of these theories, it is important that there should be comparability
94 between studies. However, signal acquisition and processing parameters have varied
95 between studies involving isometric force production (Table 1), for example the sample
96 frequency used varies by an order of magnitude, and the filter cut-off frequency varies
97 by two orders of magnitude. The present study was motivated by an inability to
98 replicate previously reported patterns of ApEn values across effort levels [12] where
99 different signal sampling and post-processing characteristics were used. No previous
100 study has examined how changing these characteristics affects the conclusions drawn
101 from isometric force records. It is entirely possible that signal acquisition and
102 processing parameters may interact with the ApEn parameters [13].

103

104 The ApEn statistic is a biased estimator of the limiting parameter as are virtually all
105 non-linear statistical estimators [6]. Pincus [4] has demonstrated that with appropriate
106 parameters ApEn can distinguish between different signal types. Chon et al. [14]
107 proposed that 'r' should be set such that the ApEn value is maximized. However, ApEn
108 is intended for use with a fixed experimental protocol, fixed data length, and fixed 'm'
109 and 'r' parameters so that comparisons can be made between subjects and or
110 conditions. It is not expected that the absolute ApEn value can be compared for
111 different signal acquisition and processing settings. Consequently the approach used
112 here was to determine the effect of these settings by empirically comparing the pattern
113 of mean ApEn values across a range of isometric effort levels for a group of subjects.
114 A similar approach has been used in other areas such as endocrinology [13]. By
115 collecting the force signals at each effort level for each subject with high force and
116 temporal resolution post-processing then allows the simulation of the effects of various
117 parameter choices. Therefore, the purpose of this study was to answer, for the first
118 time, the following questions to determine how conclusions drawn from data may
119 change with different parameter choices.

120 1) What frequencies are present in isometric force signals?

121 2) What is the effect on ApEn of altering the parameters 'r' and 'm' for isometric force
122 records?

123 3) What is the effect on ApEn of different sampling frequencies?

124 4) What is the effect on ApEn values of different filter cut-off frequencies?

125 5) Are the changes in ApEn with decimation an effect of having fewer data points or is
126 it related to the frequencies that are captured?

127 6) What is the effect of using a minimum variance criterion to select the section of data
128 for analysis, compared with alternative criteria?

129 The eventual aim was to identify a “gold standard” for the acquisition and processing of
130 isometric force records, where the purpose is to distinguish effort levels from each
131 other.

132

133 Having identified suitable acquisition, processing and parameter choices the purpose
134 was then to identify how the regularity of the force signal, as quantified by ApEn, varied
135 with effort level over a range from 5% of maximum voluntary contraction (MVC) to 75%
136 MVC.

137

138 **MATERIALS AND METHODS**

139

140 ***Participants***

141 Twenty-three, neurologically healthy subjects (range 18-72 years; 13 females and 10
142 males) were recruited to the study. All subjects were assessed for hand dominance by
143 the Edinburgh Handedness Inventory [[15](#)], and all testing was performed on the non-
144 dominant hand. Potential subjects were excluded if they had history of a serious hand
145 injury, suffered from arthritis affecting the hand, had untreated high blood pressure or
146 were taking any medications known to have neurological side effects. If required
147 subjects wore their prescription lenses through all testing procedures. All subjects

148 gave written informed consent for the experimental procedures, which had been
149 approved by the Aberystwyth University Ethics Committee for Research Procedures.

150

151 ***Testing Apparatus***

152 Participants sat upright on a non-adjustable chair (height = 45 cm) facing a 60 cm
153 computer monitor, which was placed approximately 70 cm away and centered both
154 horizontally and vertically from the eyes. The participants non-dominant hand was
155 pronated and lay flat, resting on a custom made metal plate to which a load cell was
156 attached. The non-dominant elbow was flexed to 90 degrees, and the upper arm
157 slightly abducted. A restraining plate was positioned between the second and third
158 phalanges of the hand to restrict motion of the remaining phalanges. The load cell and
159 thumb rest were positioned so that the load cell was level with the lateral side of the
160 proximal inter-phalangeal joint with the angle between thumb and index finger being
161 approximately 80 degrees when the finger was in contact with the load cell (Figure 1).
162 This set-up permitted measurement of the forces during index finger abduction, an
163 action produced entirely achieved by the first dorsal interosseus. The initial trial hand
164 position was traced so that hand position was standardised from trial to trial.

165 <<<Insert Figure 1 Around Here.>>>

166 The signal from the load cell (HBM, PW6-CC3MR/10 kg, Hottinger Baldwin
167 Messtechnik, Harrow, UK Ltd.; sensitivity 2.2 mV/V) was passed through an HBM AED-
168 9101-B full bridged transducer (Hottinger Baldwin Messtechnik, Harrow, UK). The
169 force signal was sampled at 1200 Hz, designed to reflect the sample frequency used if
170 force and electromyographic data are collected synchronously (e.g. [\[10\]](#)).

171

172 ***Familiarisation Procedure***

173 Each participant was asked to attend a familiarisation session a few days prior to the
174 test day. At the beginning of each session participants performed a warm-up of light
175 finger exercises such as flexing and extending the fingers. During the familiarisation
176 session the participant's maximum voluntary contraction force (MVC) was measured in
177 order to avoid fatigue during the experimental testing session. To measure MVC the
178 participant increased the finger abduction force gradually over approximately 5 seconds
179 until they were pushing as hard as possible and then held the maximum force possible
180 for 2-3 seconds. The force applied to the load cell was displayed on the monitor in
181 white pixels. The time count was displayed on the screen and verbal encouragement
182 was given during each trial. After two practice trials a further three maximum effort
183 trials were performed. Between each trial the participant was given a 3 minute rest.
184 The maximum force from the three recorded trials was the MVC.

185

186 Following this each participant practiced a number of the force targeting trials, which
187 included familiarisation with the targeting of the force trajectory at force levels varying
188 from 5% to 75% of MVC. The display was re-scaled for each subject so that the force
189 target was displayed as a percentage of maximum from 0-100% to avoid possible
190 effects on resolution due to scaling.

191

192 ***Testing Procedure***

193 At a subsequent session participants produced isometric contractions at 5%, 10%,
194 25%, 40%, 50% and 75% of their MVC for ten seconds. A three minute rest was given
195 after trials of 50% and 75% MVC, otherwise a one minute rest was given. The order of
196 presentation of the effort levels was randomised. Participants were informed what the
197 force target would be prior to each trial and were instructed to ramp-up the contraction
198 from 0% as quickly as possible to the target.

199
200 The target was a force level identified by two red lines displayed on a computer
201 monitor, the top line two pixels thick and bottom line four pixels thick. The gap between
202 the red lines was scaled to be $\pm 5\%$ of the target force. In order to maintain a visible
203 gap between the lines at the lowest force levels a minimum gap of a six pixels was
204 used, which represented an error window of $\pm 20\%$ at 5% MVC, and $\pm 10\%$ error at 10%
205 MVC. The participant viewed their force trajectory as a white force time trajectory two
206 pixels thick moving from left to right across a black background. The participants were
207 instructed to keep the white trajectory line between the red lines, but were told to focus
208 on keeping the line as 'straight and steady' as possible.

209

210 ***Post Processing***

211 All data processing was performed using custom software written in Matlab v9.9
212 (MathWorks, Inc., Natick, MA). Electrical noise was removed using a 49.0-51.0 Hz 4th
213 order (bi-directional) Butterworth notch filter. Unless otherwise stated, a rolling
214 minimum variance window was used to select the steadiest three second section of
215 each data set for subsequent analysis. ApEn was computed for each trial using the

216 method described by Pincus [4]. ApEn quantifies the negative natural logarithm of the
 217 conditional probability that a template is repeated during a time series. ApEn(m,r,N),
 218 takes sequences of m data points and determines the logarithmic likelihood that this
 219 sequence is similar to other sequences of data points in the data set. Matching
 220 templates that remain similar (i.e. within the tolerance, r) are then counted, the number
 221 of matches to the ith template of length m is designated B_i. Then the number of these
 222 matches that remain similar for the m+1th point is counted, this number for the ith
 223 template is designated A_i. When comparing sequences they are considered to be
 224 similar if the sequences differ by an amount greater than the noise threshold r. The
 225 approximate entropy can then be computed from,

$$ApEn(m,r,N) = \frac{1}{N-m} \sum_{i=1}^{N-m} \log \frac{A_i}{B_i}$$

227 Where,

228 N – number of data points in time series

229 m – length of template

230 A_i – number of matches of the ith template of length m+1 data points

231 B_i – number of matches of the ith template of length m data points

232

233 Several different processing conditions were applied to the force data in post-
 234 processing to answer the questions posed about the effect of signal acquisition and
 235 processing choices on the ApEn values. The effect that each condition had on
 236 calculated ApEn values was determined from the mean results and the associated

237 confidence interval for all subjects across different isometric effort levels. The
238 processing conditions applied were as follows.

239

240 1) What frequencies are present in isometric force signals? Frequency analysis of the
241 measurement system from trials with no load and a known load on the force sensor,
242 and the spectra of the subjects' trials was carried out in order to identify frequencies
243 present in the signal that are due to physiological processes.

244

245 2) What is the effect on ApEn of altering the parameters ' r ' and ' m ' for isometric force
246 records? The parameter ' r ' was altered from the Root Mean Square (RMS) of the
247 measured noise ($r=1.13N$, determined by collecting force signal data with no force
248 exerted and with a known load), to using 0.1 of signal standard deviation (SD), and 0.2
249 SD of the force signal of each trial, ' m ' was increased from 2 to 3.

250

251 3) What is the effect on ApEn of different sampling frequencies? The original signal
252 sampled at 1200 Hz was decimated to 600 Hz, 200 Hz, 100 Hz and 30 Hz to simulate
253 lower sampling frequencies. In the decimation process the original data set is filtered
254 to remove signal frequency components above the Nyquist frequency to be simulated,
255 and then the signal is resampled. To mirror an approach sometimes used in the
256 literature the 1200 Hz was also downsampled, that is: resampled to produce a 100 Hz
257 signal, but without the filtering.

258

259 4) What is the effect on ApEn values of different filter cut-off frequencies? The original
260 signals were low-pass filtered using 4th order bi-directional Butterworth filters, with cut-
261 off frequencies of 100 Hz, 80 Hz, 70 Hz, 60 Hz, 50 Hz, 30 Hz and 25.6 Hz. The cut-off
262 frequencies were selected to mirror values used in the literature and the frequencies
263 associated with motor unit activity (Table 1).

264

265 5) Are the changes in ApEn with decimation an effect of having fewer data points or is
266 it related to the frequencies that are captured? The size of the minimum variance
267 window was altered to capture the number of data points that equalled the total number
268 of data points in each decimated data set. For example, decimating a three second
269 length of data sampled at 1200 Hz to 30 Hz reduces the number of points from 3600 to
270 90 data points. Therefore the minimum variance window was adjusted to collect just 90
271 data points. This method was used to simulate the collection of 1800, 300 and 90 data
272 points (the number of data points equivalent to sampling at 600 Hz, 100 Hz and 30 Hz
273 respectively). In addition, the steadiest five seconds, three seconds and half a second
274 of the force data (starting from the fourth second) were selected from each trial in order
275 to assess the effect of varying N on ApEn values.

276

277 6) What is the effect of using a minimum variance criterion to select the section of data
278 for analysis, compared with other criteria? A 3 s window extracted using a minimum
279 variance criterion was compared to a 3 s window starting from the fourth second, and
280 to a 3 s window starting at the sixth second, and to half second windows starting at the
281 fourth, sixth or eighth second of data. Since the first three seconds of data was always

282 removed to allow for ramping up to the correct force level, there were seven seconds of
283 data (from the 3rd to the 10th second) available for analysis.

284

285 Finally, once reasonable values for the parameters had been chosen, the relationship
286 between effort level as a percentage of MVC and regularity as quantified by ApEn was
287 determined. An Analysis of Variance and post-hoc Tukey tests were used to identify
288 for which force levels the regularity differed. The significance level for all statistical
289 tests was set at $p=0.05$.

290

291

RESULTS

292

293 Typical force-time records are shown for a contraction at 5% of MVC, and a contraction
294 by the same subject at 75% of MVC (Figure 2).

295

<<Insert Figure 2 around here>>

296 1. What frequencies are present in isometric force signals?

297 The frequency spectra of force for contractions at 5 to 75 % had the majority of the
298 power below 15 Hz, but the power in the signals between 15 and 30 Hz did increase
299 with changing percentage of MVC (Figure 3). For example, the proportion of the signal
300 power in the 0 to 15 Hz band compared with the 15 to 30 Hz band was twice as great
301 for the 75% signal compared with the 25% signal. The power spectrum for the force
302 sensor was constant and low across all frequencies (Figure 3a), and so did not
303 demonstrate changes in power with increases in frequency, thus the changes in signal
304 power content with increasing percentage of MVC were biological in origin.

305 <<Insert Figure 3 around here>>

306 2) What is the effect on ApEn of altering the parameters ' r ' and ' m ' for isometric force
307 records?

308 Changing the ' r ' parameter had a large effect on the pattern of ApEn results across the
309 range of effort levels (Figure 4). Using a value for ' r ' which was obtained from an
310 analysis of the amplitude of the noise of the transducer resulted in a sigmoid like curve
311 across the range of effort levels. However, increasing the value of the ' r ' parameter to
312 0.2 of the standard deviation of each signal resulted in a flattening of the pattern of
313 ApEn values across the range of effort levels. Changing the ' m ' parameter from 2 to 3
314 reduced the ApEn values but preserved the pattern of values across the force levels
315 (Figure 5).

316 <<Insert Figures 3 and 4 around here>>

317 3) What is the effect on ApEn of different sampling frequencies?

318 Down-sampling and decimation of the data to replicate sampling frequencies below 200
319 Hz reversed the trend of ApEn values across the range of effort levels (Figure 6).

320 <<Insert Figure 6 around here>>

321 4) What is the effect on ApEn values of different filter cut-off frequencies?

322 For sample rates above 200 Hz, changing the filter cut-off frequency had little effect.
323 Very small decreases in the absolute ApEn values were seen with decreases in the
324 filter cut-off frequency from 80 to 25.6 Hz (Figure 7). The patterns of ApEn values
325 across the range of effort levels were identical.

326 <<Insert Figure 7 around here>>

327 5) Are the changes in ApEn with decimation an effect of having fewer data points or is it
328 related to the frequencies that are captured?

329 When the data is downsampled to produce a signal sampled at 100 Hz or 30 Hz, the
330 ApEn pattern changes considerably (Figure 8a). However, a three second data record
331 at 100 Hz is 300 data points long, and at 30 Hz is 90 data points long. When sections
332 of data of length 300 points, and 90 points are taken from the original signal sampled at
333 1200 Hz without downsampling, it can be seen that the pattern of ApEn results over the
334 effort levels does not change, although the absolute ApEn values change slightly
335 (Figure 8a). This suggests that the dramatic change in pattern seen when the data is
336 decimated or downsampled (Figure 6) is related to the frequencies captured and not
337 the number of data points analysed.

338

339 6) What is the effect of using a minimum variance criterion to select the section of data
340 for analysis, compared with an alternative criterion?

341 When a fixed section of the data record is taken, for example from the 3rd to the 6th
342 second, as opposed to using the minimum variance criterion to select the same data
343 length, there is very little effect on either the absolute ApEn values, or the pattern of
344 values across the effort levels (Figure 8b).

345 <<Insert Figure 8 around here>>

346 Finally, with 'r' set at the level of transducer noise, 'm' set to 2, the sample rate set to
347 1200 Hz, and a data length of 3 seconds selected using the minimum variance
348 criterion, there was a significant effect for effort level on ApEn(2, (F=44.39; d.f.=5, 105;
349 p<0.001). Post-hoc Tukey comparisons showed that effort levels of 5, 10 and 25%

350 MVC were significantly different from effort levels of 40, 50 and 75% MVC ($p < 0.001$).
351 In general the ApEn value increased with increasing effort level (Figures 3-7).
352 Conversely, with ' r ' set at 0.1SD the ApEn value generally decreased with increasing
353 effort level (Figure 4) ($F = 16.69$; d.f. = 5, 110; $p < 0.001$). Post-hoc Tukey comparisons
354 showed that the effort levels of 5% and 10% MVC were significantly different from the
355 other effort levels, and that 25% and 40% MVC were significantly different from 50%
356 and 75% MVC ($p < 0.001$).

357

358

DISCUSSION

359

360 This study determined the effect of different sampling and post-processing choices on
361 the pattern of ApEn values for isometric force records across a range of effort levels
362 produced by the First Dorsal Interosseus in order to identify what effect these may have
363 on conclusions drawn when using ApEn to differentiate between force levels. This
364 study has shown that choosing an appropriate value for the ' r ' parameter in the ApEn
365 algorithm is very important. The role of this parameter is to account for measurement
366 system noise. The choice of ' r ' for a given process or physiological setting, is
367 influenced by physiological attributes (the focus of the present study), the series length,
368 N , and the sampling frequency. The sampling frequency also strongly determines the
369 entropy value due to the mathematical underpinnings of the calculation of ApEn.

370

371 When examining the variability of beat by beat heart rate data it has been
372 recommended that ' r ' be set to between 0.1 and 0.25 of the SD of the time series [5].

373 However, for heart rate data it can be more difficult to estimate the noise of the
374 measurement system since it arises from several sources. For a force transducer that
375 is well shielded and has a differential input amplifier the noise level should be very low,
376 and measurable. In addition, when comparing beat by beat data, it is likely that the
377 standard deviation of data from different subjects is fairly similar [16]. This is partly due
378 to the physiological limits of the heart which mean that the range of frequencies is low
379 (the extreme range of 30 to 220 beats per minute is equivalent to a range of just 0.5 to
380 3.67 Hz). In contrast, the standard deviations of the force signals here increased by
381 orders of magnitude moving from 5% to 75% MVC. This means the pattern of ApEn
382 values is flattened across the range of effort levels as ' r ' is increased through 0.1 to 0.2
383 SD (Figure 4). The proposal of Chon et al. [14] that ' r ' should be set such that the
384 ApEn value is maximized, if applied across the full set of force records for all effort
385 levels and subjects was approximately the same as the amplitude of the transducer
386 noise, i.e. the low and fixed ' r ' value (1.13N) used here.

387

388 A primary finding of this study was that a fixed ' r ' value reflecting measurement system
389 noise results in a strong discrimination between different processes in the analysed
390 signal, which is consistent with previous work [13]. An important point is that ApEn with
391 a fixed ' r ' value captures changes in both complexity and variance [17]. It is often the
392 case that ApEn increases with increasing variance [17]. To decouple ApEn from the
393 variance, Pincus and Goldberger [17] suggested that 'normalized regularity' could be
394 obtained by setting ' r ' to a fixed percentage of the standard deviation. Both versions of
395 ApEn have their uses but have a slightly different focus from each other [18].

396

397 The direction of the relationship between ApEn and effort levels reverses when ' r ' is
398 reduced from 0.1 SD to a level equivalent to measurement system noise ($r=1.13N$). A
399 similar phenomenon was shown by Pincus and Huang [6] who mathematically
400 constructed a pair of processes denoted the 'flip-flop pair'. Their conclusion was that
401 different relative dynamic characteristics can be manifested as the resolution
402 (controlled by reducing the ' r ' value) is altered. Using this reasoning it may be
403 concluded that with a fixed ' r ' that is similar to measurement system noise, it is possible
404 to distinguish between effort levels above 40% and below 25% of MVC. When the
405 normalized regularity is assessed (i.e. using ' r ' set to 0.1SD) it is possible to distinguish
406 between effort levels below 10% versus effort levels above 25% MVC, and to
407 distinguish between 40% versus 75% MVC. However it is not possible to distinguish
408 between all effort levels using only one ' r ' value.

409

410 The second key setting identified here was the choice of sample frequency. Figure 6
411 shows that sample frequencies below around 200 Hz, whether obtained by decimation
412 (filtering before downsampling to prevent aliasing) or simple downsampling (taking
413 every n^{th} point without prior filtering) changes, and for very low sample rates,
414 completely reverses the pattern of mean ApEn values across the effort levels. Veldhuis
415 et al. [13] used a similar approach to the present study when examining the effect of
416 varying sampling frequency on ApEn applied to hormonal secretory patterns. Their
417 study also showed that a high sampling frequency is required for delineation using
418 ApEn of records arising from models with different dynamics.

419

420 The pattern of decreasing complexity with increasing effort level seen with the 30 Hz
421 sample rate seems unrealistic when the appearances of the plots for 5% and 75% of
422 MVC are considered (Figure 2). Furthermore, this sample rate would not allow
423 frequencies above 15 Hz to be captured without aliasing. For frequencies above 200
424 Hz, the pattern of mean ApEn values across the effort levels is preserved, although a
425 reduction in the actual values is seen. Comparison of Figure 6 with Figure 8 shows
426 that the change in pattern for low sample frequencies is not simply due to the reduction
427 in the number of data points when a lower sample rate is used. For example, the
428 pattern of mean ApEn values clearly changes when the sample frequency is changed
429 to 100 Hz, at this frequency 300 data points constitute the 3 second window, whereas
430 at 1200 Hz the three second window is 3,600 data points long. However, when the
431 ApEn value of 300 sequential data points from the data series sampled at 1200 Hz is
432 computed it can be seen that although the ApEn value is reduced, the pattern of mean
433 values across the effort levels is preserved. The greater relative sensitivity of the ApEn
434 algorithm to the sample frequency as opposed to the number of data points should not
435 be surprising given the theoretical relationship between entropy rate and scalar
436 multiples of sample frequency [17].

437

438 It can be seen from Figure 8b that, once a steady state force has been achieved, the
439 criterion used to select the data window for analysis has little effect on either the
440 pattern of ApEn values or the actual ApEn values. The length of the data series also
441 has little effect on the pattern of ApEn values, though for very short data series the

442 ApEn values are slightly reduced for the highest effort levels. Also, once a suitably
443 high sample rate, and a suitable value for the ' r ' parameter had been set, it was found
444 that the pattern of mean ApEn values was robust to changes in the ' m ' parameter.
445 Finally, once a suitably high sample rate, and a suitable value for ' r ' had been set, the
446 filter cut-off frequency had little effect on either the pattern or the actual values; this
447 may be expected since the ' r ' parameter, if appropriately set, acts as a filter. The
448 robustness to a range for the ' m ' parameter is reasonable given the formulation of the
449 ApEn algorithm [17]. It is reassuring that the pattern of results is also reasonably
450 robust to small alterations in the location and length of the window of data for analysis.

451

452 ApEn has been widely used to draw conclusions about the structure of isometric force
453 records and possible differences, for example, with age [19], task [20], pathology [21],
454 and feedback [22]. However, previous studies have used very different signal
455 acquisition and processing settings and have used different parameter settings, even
456 for the same task. The results of this study show that certain sampling and parameter
457 choices can completely reverse conclusions with respect to the regularity of isometric
458 force records at different effort levels. The present study did not identify the same
459 inverted U relationship reported by Slifkin and Newell [12]. While the present study
460 involved finger abduction, which is entirely achieved by the first dorsal interosseus, the
461 Slifkin and Newell [12] study measured index finger flexion, for which it is the prime but
462 not the sole mover. However, given the results of the present study, it is also possible
463 that the discrepancy is due to their sample rate of 100 Hz, which, based on the present

464 findings, would reduce the ApEn value of the highly variable trials at the higher effort
465 levels towards zero.

466

467 The difference in regularity with fixed ' r ', ApEn($m=2$, $r=1.13N$, $N=3600$), between effort
468 levels above and below 40% found in the present study may be associated with the
469 different force gradation strategies for the first dorsal interosseus [12, 23]. Below 30-
470 40% MVC force gradation is primarily achieved by motor unit recruitment, at higher
471 effort levels it is achieved primarily by rate coding [24]. As previously described,
472 ApEn($m=2$, $r=1.13N$, $N=3600$) reflects the change in regularity and variance jointly. It is
473 noteworthy that the degree of regularity is comparable at 40 and 75% of MVC, despite
474 the magnitude of the fluctuations (quantified by the standard deviation of force) being
475 twice as high for 75% MVC and statistically significantly different to 40% MVC.
476 Conversely ApEn($m=2$, $r=0.1SD$, $N=3600$) is lower for 75% than for 40%, suggesting
477 that the apparently greater randomness using ApEn($m=2$, $r=1.13N$, $N=3600$) is linked
478 to the higher variance of the force record at 75% MVC.

479

480 The results of the present study suggest that a change in the force gradation strategy
481 can be identified using ApEn with ' r ' fixed and equivalent to the measurement system
482 noise. This metric shows that in the region of motor unit recruitment, the force record
483 during isometric contraction is highly ordered, but exhibits less regularity or greater
484 randomness in the region of rate coding. Furthermore it is possible to distinguish
485 between effort levels below 10% and above 10%, and to distinguish between 40% and
486 75% MVC by using ApEn with ' r ' set to 0.1SD. This metric may reflect an inflection

487 point in the motor unit firing rate versus effort level relationship. Such inflection points
488 can be seen in the motor unit firing rate versus force level plots presented by De Luca
489 and Erim [25]. While EMG studies indicate the patterns of motor unit recruitment in the
490 FDI [26], simulation studies of motor unit activation patterns and the corresponding
491 changes in the nature of force output demonstrate that these variations are caused by
492 multiple mechanisms [9]. There are other mechanisms which will contribute these
493 force fluctuations, for example muscle forces will cause corresponding changes in
494 tendon stretch causing changes in muscle length and therefore muscle force. At low
495 muscle forces these tendon length changes may not be influential because of the low
496 stretch caused in the toe-region of the tendon stress-strain curve [27]. The pattern of
497 results seen in this study characterize the FDI, but the relationship between motor unit
498 firing rate and force relationship differ between muscles, for example there is a distinct
499 difference in this pattern for the FDI [24] and the Vastus Medialis [28]. The methods
500 proposed in this study would be applicable to other muscles, but may potentially reveal
501 different mechanisms associated with force variability.

502

503 In conclusion, based on the findings of this study, when computing ApEn it is
504 recommended isometric force records are sampled at frequencies >200 Hz, ' m ' is set to
505 2, and ' r ' is set using estimated measurement system noise or $0.1SD$ depending on the
506 effort levels to be distinguished. Using these values, it has been shown that significant
507 ApEn differences existing at effort levels corresponding to a change in force gradation
508 strategy. The relationship between the structure of the variability and the force

509 gradation strategy for this muscle provides a basis for using ApEn to detect and
510 understand changes in neuro-muscular physiology with ageing, pathology and training.

LIST OF FIGURES

Figure 1: Experimental set-up showing hand and index finger position.

Figure 2: Typical isometric force records from one subject at 75%, 50%, 25%, and 5% MVC.

Figure 3: Typical frequency spectra for a) the steady state section of isometric force records at various effort levels, and b) for two exemplar effort levels and the transducer noise when loaded with a fixed mass (expanded view). Note that the noise is so low in magnitude compared to the other signals that it is barely visible in a).

Figure 4: Mean (error bars show 95% confidence interval for the mean) ApEn values across the range of effort levels when the ‘ r ’ parameter is set equal to the amplitude of the transducer noise, or equal to 0.1 or 0.2 times the standard deviation of the force record, and ‘ m ’=2 and N=3,600.

Figure 5: Mean (error bars show 95% confidence interval for the mean) ApEn values across the range of effort levels when the ‘ m ’ parameter is set to 2 or 3, and ‘ r ’ is set to the amplitude of the transducer noise and N=3,600.

Figure 6: Mean (error bars show upper bound of 95% confidence interval for the mean) ApEn values across the range of effort levels when the sample frequency is

636 1200 Hz (Undec) or decimated to 600 Hz (Dec600) to 200 Hz (Dec200) to 100 Hz
637 (Dec100) to 30 Hz (Dec30) or is simply downsampled to 100 Hz (DOWN). The '*m*'
638 parameter is set to 2, and the '*r*' parameter is set to the amplitude of the transducer
639 noise.

640

641 **Figure 7:** Mean (error bars show upper bound of 95% confidence interval for the
642 mean) ApEn values across the range of effort levels when the sample frequency is
643 1200 Hz and the filter cut-off frequency is set to values between 25.6 Hz and 80 Hz.
644 The '*m*' parameter is set to 2, and the '*r*' parameter is set to the amplitude of the
645 transducer noise and $N=3,600$.

646

647 **Figure 8:** Mean (error bars show upper bound of 95% confidence interval for the
648 mean) ApEn values across the range of effort levels for a) data decimated to replicate
649 sampling at 100 and 30 Hz and also data records of the same length (number of points)
650 but sampled at 1200 Hz, and b) data records sampled at 1200 Hz of various lengths.
651 In (b) the data is either extracted using a minimum variance criterion, or is taken from a
652 fixed section of the data: for the 5 second record this is from 4 to 9 seconds, for the 3
653 second record this is from 4 to 7 seconds, for the 0.5 second record this is either from
654 early in the record (4 to 4.5 seconds) or from late in the record (6 to 6.5 seconds). The
655 '*m*' parameter is set to 2, and the '*r*' parameter is set to the amplitude of the transducer
656 noise.
